Logical Foundations of Evidential Support

Branden Fitelson[†‡]

Carnap's inductive logic (or confirmation) project is revisited from an "increase in firmness" (or probabilistic relevance) point of view. It is argued that Carnap's main desiderata can be satisfied in this setting, without the need for a theory of "logical probability." The emphasis here will be on explaining how Carnap's epistemological desiderata for inductive logic will need to be modified in this new setting. The key move is to abandon Carnap's goal of bridging confirmation and *credence*, in favor of bridging confirmation and *evidential support*.

1. Setting the Stage: Three Carnapian Desiderata. In the second edition of *Logical Foundations of Probability* (*LFP*), Carnap (1962, xvi) distinguished two kinds of inductive-logical confirmation relations: *confirmation as firmness*, which he informally characterized as "how probable the hypothesis H is on the basis of the evidence E," and *confirmation as increase in firmness*, which he informally characterized as "how much the probability of H is increased when new evidence E is acquired (in addition to the prior evidence which, for simplicity, we shall take here as tautological)." Carnap devotes almost all of *LFP* to the task of explicating the former. Presently, I will discuss Carnap's approach to the former and sketch my own approach to the latter. My discussion will focus, ultimately, on the relation between inductive logic (the confirmation as increase in firmness relation) and epistemology (the relation of incremental evidential support).

I begin with some quotes from *LFP* to set the stage. The first gives a general sense of the very idea of inductive logic, as a quantitative analogue (or generalization) of deductive logic:

> Deductive logic may be regarded as the theory of the relation of logical consequence [$\vdash$], and inductive logic as the theory of another concept [c] which is likewise objective and logical . . . degree of confirmation (Carnap 1962, 200).

The next two quotes give Carnap's (1962, 200) informal characterizations of the terms 'logical' and 'objective' as they apply to the relations $\vdash$ and c:

> The principal common characteristic of the statements in both fields is their independence of the contingency of facts. This characteristic justifies the application of the common term 'logic' to both fields.

> That c is an objective concept means this: if a certain c value holds for a certain hypothesis with respect to a certain evidence, then this value is entirely independent of what any person may happen to think about these sentences.

It is clear that Carnap, at least, intends here to be saying that confirmation relations should be *analytic*. But, *mere analyticity* is not all that is required of confirmation. Confirmation (c) must be analogous to entailment ($\vdash$) in certain *other* ways as well. Specifically, Carnap (1962, 202) adds:

> They both involve the concept of range. 'E L-implies H' ['$E \vdash H$'] means that the entire range of E is included in that of H, while . . . '$c(H, E) = 3/4$' means three-fourths of the range of E is included in that of H.[1]

Moreover, Carnap emphasizes that both relations ($\vdash$ and c) should be applicable to *epistemology* in analogous ways. He endorses analogous *epistemic bridge principles* for both relations. For the $\vdash$ relation, Carnap (1962, 201) endorses the following closure principle:

> If E is known by the person X at the time t, then H is likewise known by X at t [provided that $E \vdash H$ is also known by X at t].

For c, Carnap (1962, 201) endorses the following principle, which he takes to be *analogous* to closure:

1. Here, Carnap has in mind confirmation as *firmness*. We'll have to generalize this 'range' analogy with entailment when we discuss confirmation as *increase in firmness* below.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

> If *E and nothing else* is known by *X* at *t*, then the degree of belief justified by the knowledge of *X* at *t* is 3/4 [provided that $\mathfrak{c}(H, E) = 3/4$ is also known by *X* at *t*].

For Carnap, then, inductive logic involves a confirmation relation $\mathfrak{c}$, which has (at least) the following three characteristics (I take these to be neutral between the firmness and increase in firmness conceptions of confirmation):

- *Analyticity*: Statements involving $\mathfrak{c}$ should be *analytic*, like statements involving $\vdash$ are.

  > Carnap had a philosophical theory of analyticity. We will not worry too much here about the details of his theory of analyticity (since that is not our emphasis). Roughly, here we will (following the spirit of Carnap's informal characterizations of analyticity rather than the letter of his technical theory thereof) take 'analytic' to mean "true in the way that mathematical truths are true."

- *Logicality*: $\mathfrak{c}$ should be a *quantitative generalization* of $\vdash$.

  > $\mathfrak{c}(H,E)$ should be maximal (minimal) when $E \vdash H$ ($E \vdash \sim H$).[2]

- *Applicability*: $\mathfrak{c}$ should be *applicable to epistemology* in ways analogous to the ways in which $\vdash$ is applicable to epistemology.

  > Some kind of *epistemic bridge principle(s)* should hold, which connects $\mathfrak{c}$ with some epistemic concept (much more on this below).[3]

2. Carnap's Approach to Confirmation as Firmness. Carnap's $\mathfrak{c}(\cdot, \cdot)$'s are, basically, measures of the relative frequencies with which certain syntactical particles occur in the sentences of certain simple formal lan-

2. That is, so long as the function $\mathfrak{c}(H, E)$ is *defined*. I am ignoring the paradoxes of entailment (see below). I have generalized Carnap's "logical range" analogy, since that analogy breaks down when we are talking about *increase in firmness*. I have settled on this desideratum, since it is the strongest one I can think of that is capable of meaningfully applying to both the firmness and the increase in firmness conceptions of confirmation.

3. As we will see below, Carnap has other epistemic applicability requirements in mind, which go beyond mere "epistemic bridge principles." I will not comment too much on these additional desiderata here, as this would require a much longer and involved treatment.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

guages.[4] The building blocks of early Carnapian $\mathfrak{c}$'s are "regular logical measure functions" $\mathfrak{m}(\cdot)$. Such $\mathfrak{m}$'s assign numbers on (0, 1) (which sum to 1) to each of the *state descriptions* ($\mathfrak{Z}$) of some (monadic) first-order language $\mathfrak{L}$. In his earliest system, Carnap uses $\mathfrak{m}^{\dagger}(\cdot)$, which assigns *equal measure* to each *state description* in $\mathfrak{L}$. Conditional "logical" probability ($\mathfrak{c}^{\dagger}$) is then given by a *ratio* of these unconditional logical probabilities (in the usual way): $\mathfrak{c}^{\dagger}(H, E) = [\mathfrak{m}^{\dagger}(H\&E)]/[\mathfrak{m}^{\dagger}(E)]$. This function $\mathfrak{c}^{\dagger}$ satisfies the first two desiderata above, because (i) $\mathfrak{c}^{\dagger}$ statements are *analytic*, since, *given* $\mathfrak{m}^{\dagger}$, they are determined by the structure of $\mathfrak{L}$; and (ii) $\mathfrak{c}^{\dagger}$ *generalizes entailment*, since $\mathfrak{c}^{\dagger}$ is maximal (minimal) when $E \vdash H$ ($E \vdash\sim H$).[5] Nonetheless, Carnap eventually *rejects* $\mathfrak{c}^{\dagger}$, because he thinks its *applicability to epistemology* is unsatisfactory. Interestingly, this is *not* because $\mathfrak{c}^{\dagger}$ fails to undergird his desired epistemic bridge principle. Carnap (1962, 565) explains:

> The choice of $\mathfrak{c}^{\dagger}$ as the degree of confirmation would be tantamount to the principle never to let our past experiences influence our expectations for the future.

What Carnap *means* here is that, according to $\mathfrak{c}^{\dagger}(H,E)$, no E can ever *increase the firmness* of any H (unless $E \vdash H$). That is, we can never have $\mathfrak{c}^{\dagger}(H, E) > \mathfrak{c}^{\dagger}(H, T)$, unless $E \vdash H$.[6]

Because of this "no learning from experience problem," Carnap abandons $\mathfrak{c}^{\dagger}$ in favor $\mathfrak{c}^{*}$, a function constructed using a *different* measure function $\mathfrak{m}^{*}$, which in turn assigns equal measure to the *structure descriptions* ($\mathfrak{Str}$) of $\mathfrak{L}$. The structure descriptions of $\mathfrak{L}$ are just collections of state descriptions of $\mathfrak{L}$ that are invariant under permutations of individual constants. This "clumping" of state descriptions avoids the no learning from experience problem. But, Carnap thinks $\mathfrak{c}^{*}$ has other shortcomings concerning its ep-

4. Here, I have in mind Carnap's early writings on confirmation and inductive logic. Later on, he moved toward a more semantic approach and away from the early syntactic approaches to confirmation. This distinction is not terribly important for present purposes. So, because it is simpler to talk about Carnap's early approaches, that is what I will do. For a more in-depth discussion of Carnap's program along present lines, see Fitelson (2005).

5. Carnap's $\mathfrak{c}$'s get more than just the "endpoints" right; they give a tighter quantitative generalization in terms of "logical range." This cannot be achieved by measures of confirmation as increase in firmness. See Kemeny and Oppenheim (1952) for similar remarks.

6. It is somewhat strange that Carnap should see *this* as a problem for a measure of confirmation as *firmness*. But, I will let that pass. Carnap (in the early days) had a tendency to slide back and forth between considerations of firmness confirmation and considerations of increase in firmness confirmation. See Michalos (1971) for an extended discussion of this aspect of Carnap's thought and Popper's criticisms of it.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

istemic applicability. This causes Carnap to add an *adjustable parameter* λ to his c-constructions, which yields a λ-continuum of c-functions.[7] Later, Carnap puzzled over still other epistemic application requirements that he thought no cλ-function could adequately meet. This led to the addition of further adjustable parameters to his systems, which allowed Carnap more flexibility in the ways in which he could carve up his languages $\mathfrak{L}$. But, even this broader class of c's never seemed fully satisfactory to Carnap from the point of view of its epistemic applicability. In the end, the classes of probability functions that one can construct Carnap-style from such $\mathfrak{L}$'s do not seem rich enough to meet all the demands of general epistemic application (Maher 2001).

At this point, I want to step back and ask two questions:

- Why bother with such syntactic constructions in the first place?
- *Can* we *have* analyticity, logicality, *and* epistemic applicability?

3. Analyticity and Logicality on the Cheap. Carnap acts as if the *analyticity* of c *requires* its syntactical construction (within $\mathfrak{L}$) out of "logical measure functions." It is unclear why this should be true (*even if* you accept Carnap's formalistic understanding of analyticity). There seems to be an additional presupposition at work here: that the function c should be *two-place* in the same way that $\vdash$ is two-place. But, the attempt to construct a two-place c seems to have failed. Even Carnap found the need to add adjust*able* parameters to his recipes for constructing c's. And, the resulting c statements will not even be *analytic* until all of these parameters are adjusted. So, in the end, c is not *really* two-place, even for Carnap. I suggest another (more direct and general) way to ensure analyticity:

> c is a *three-place* relation between E, H, and *a probability model* (or a family thereof) $\mathcal{M}$.[8]

By making c explicitly a three-place relation in this way, we do not restrict ourselves to a *limited class* of probability models that can be cooked up using simple first-order languages $\mathfrak{L}$ according to some Carnapian recipe. This is advantageous, because there are many probability models that seem salient to statistical and inductive inference that cannot be simulated by even the most sophisticated of Carnapian constructions (Maher 2001). Note: this still

7. Basically, λ is an *index of caution*. If λ is infinite, then no learning from experience is possible: $c^{\dagger}$, and if λ is set to a certain finite value, then it yields c*, and so on.

8. By a *probability model*, I mean a boolean algebra (or sigma algebra) of propositions, together with a function satisfying whichever axioms for probability you prefer. I prefer Kolmogorov's (1933) axioms for probability, but others prefer to take conditional probability as primitive. See Hájek (2003) for discussion. This issue is not crucial for my present purposes, and so I will remain neutral on it here.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

gives us *analyticity* (even in Carnap's technical sense), since *given* $\mathcal{M}$, all probability statements—*relative to* $\mathcal{M}$—are *mathematically true*.[9] So, we can easily obtain *analyticity* (and increased generality) by making $\mathfrak{c}$ three-place rather than two-place. How about *logicality*? Yes, that's not a problem either, since, in *all* probability models $\mathcal{M}$ (Carnapian or otherwise), $\Pr_{\mathcal{M}}(H|E)$ will be maximal (minimal) when $E \vdash H$ ($E \vdash\sim H$).

However, when we make the three-place nature of $\mathfrak{c}$ explicit, the *epistemic applicability* problem becomes prominent. To see this, consider the following naive, Carnap-style bridge principle:

> If X knows E *and nothing else* (a posteriori), and X knows (a priori) that $\Pr_{\mathcal{M}}(H|E) = r$, then X's *credence* in H, given E, should be r. (This is tantamount to treating *arbitrary* probability functions as "expert probabilities" in the sense of Gaifman [1988].)

This just *cannot* be true, since if it were true, then nothing about the *relationship between* the model $\mathcal{M}$, the agent X, and/or the world would be required to constrain X's credences. Hence, this principle is implausible *even if* we understand what it means (in general) to "know E *and nothing else*." What made Carnap's bridge principle *at all* plausible (perhaps modulo the "and nothing else" clause) was that *his* models were supposed to *be models of* "a priori" probability. As such, they had their epistemic credentials *built-in* from the start. But, what if *there is no such thing* as "logical" or a priori probability (as many of us now suspect)? Does this mean that inductive logic is impossible? Not necessarily. At least, that is what I will try to argue.

4. Confirmation as Increase in Firmness Revisited. Let's return to confirmation as *increase in firmness* now. It is well known (Fitelson 2001) that there are *many* measures of the degree to which E increases the firmness

9. One might object at this point that we have obtained analyticity *too* cheaply here. After all, in this sense of analyticity the mathematical statements of mathematical physics can also be considered analytic (once we relativize them to concrete mathematical structures). This may be true, but a mathematical theory of physics needs to be more than just analytic in this sense—it also needs to be *empirically adequate, and so on*. Likewise, theories of confirmation also need to satisfy *logicality* and *applicability*. So, the fact that analyticity is "cheap" in this way does not, to my mind, undermine the philosophical significance of inductive logic so understood. One of the reasons that Carnap wanted the statements in his theory of confirmation to be analytic is that he wanted them (if true) to be knowable a priori. I do not see how this is possible if the statements are not even *determinate* until certain adjustable parameters are fixed *empirically* (as in Carnap's later systems). By making analyticity cheap in this way, we avoid this problem. A full response to this objection is beyond the scope of the present, brief discussion. This is something I plan to discuss at length in a forthcoming book on inductive logic.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

of H. Interestingly, very few of these satisfy *logicality*. We can sum up the desiderata of logicality and sensitivity to increase in firmness (or relevance) as follows. For all *contingent* E and H:[10]

$$\mathfrak{c}(H,E,\mathcal{M}) \text{ should be } \begin{cases} \text{Maximal} & \text{if } E \text{ entails } H. \\ >0 & \text{if } E \text{ and } H \text{ are } \textit{correlated} \text{ in } \mathcal{M}. \\ =0 & \text{if } E \text{ and } H \text{ are } \textit{independent} \text{ in } \mathcal{M}. \\ <0 & \text{if } E \text{ and } H \text{ are } \textit{anti}\text{correlated in } \mathcal{M}. \\ \text{Minimal} & \text{if } E \text{ entails } \sim H. \end{cases} \tag{1}$$

As it turns out, of all the *relevance measures* used or defended in the historical literature on confirmation (up to ordinal equivalence), only $l(H,E,\mathcal{M}) = \log\{[\Pr_{\mathcal{M}}(E|H)]/[\Pr_{\mathcal{M}}(E|\sim H)]\}$ and $l'(H,E,\mathcal{M}) = \log\{[\Pr_{\mathcal{M}}(H|E)]/[\Pr_{\mathcal{M}}(H|\sim E)]$ satisfy logicality.[11] And, if we impose the following additional constraint (which seems to be accepted by all historical practitioners of probabilistic confirmation theory):

$$\text{If } \Pr_{\mathcal{M}}(H|E_1) \geq \Pr_{\mathcal{M}}(H|E_2), \text{ then } \mathfrak{c}(H,E_1,\mathcal{M}) \geq \mathfrak{c}(H,E_2,\mathcal{M}).$$

Then, we get *historical uniqueness* of l.[12] That's neat. But, I do not want make too much of fuss here about *quantitative* relevance confirmation claims of the form $\ulcorner \mathfrak{c}(H,E,\mathcal{M}) = r \urcorner$, since I think the most objective claims (and the claims most analogous to entailment claims) are *qualitative* claims of the form $\ulcorner \mathfrak{c}(H,E,\mathcal{M}) \lessgtr 0 \urcorner$. Are there bridge principles relating the qual-

10. Cases in which E and/or H are not contingent are very tricky—even in deductive logic (e.g., the paradoxes of entailment). So, for simplicity, I will bracket those cases here.

11. This fact about l was known to Kemeny and Oppenheim (1952), who are (strangely) not cited by Carnap (1962) in his discussion of confirmation as increase in firmness. What I am doing here differs from Kemeney and Oppenheim in at least two respects. First, they were still working with Carnap-style theories of "logical probability," which I have abandoned. And, second, they do not discuss the problem of epistemic applicability, which is a crucial problem that any adequate account of inductive logic must address.

12. By 'historical uniqueness', I mean only that l (or its ordinal equivalents) are the only *historically proposed and/or defended* measures (up to ordinal equivalence) that satisfy all of our present desiderata. To get *mathematical* uniqueness, one would need to make some rather strong continuity assumptions, which have no intuitive connection to material desiderata for inductive logic. Such dubious mathematical assumptions are used by Good (1960) and Milne (1996) for precisely this purpose. See Halpern (1999) for a nice critical discussion of these sorts of arguments and the implausibility of the continuity assumptions they require. I prefer not to appeal to any such purely mathematical conditions. This is why I talk in terms of historical uniqueness rather than mathematical uniqueness. I am open to the possibility that additional material desiderata will be discovered, which will narrow the field even further. That, it seems to me, is how scientific investigation should work.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

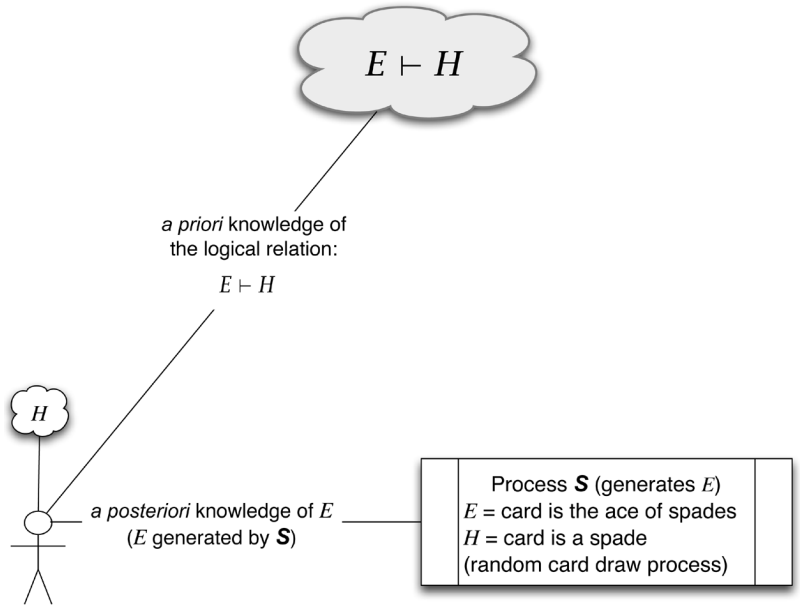

Figure 1. Entailment and knowledge.

itative *increase in firmness* confirmation relation and some epistemically important relation? I think so. But, these principles will *not* bridge confirmation as increase in firmness and *credence* (since confirmation as increase in firmness measures are not *probability* functions). Rather, they will bridge confirmation and (incremental) *evidential support*. Moreover, I suspect that there are also *comparative* bridge principles, which bridge comparative confirmation claims and comparative claims about evidential support (but these will be more controversial). Let us look at the qualitative case first.

It is useful here to compare the deductive and inductive cases. In the deductive case, the bridge principle is rather simple. If a rational agent knows $E \vdash H$ and E, then (ceteris paribus) they may be said to know H on the basis of E.[13] Figure 1 allows us to picture a concrete example.

13. I do not mean to endorse a totally naive closure principle for knowledge. This is a principle Carnap endorsed, and I am merely trying to tell a "Carnap-style" story here about firmness *versus* increase in firmness confirmation. To make this bridge principle more plausible, we would need to add various caveats, of course. I will not worry too much about such caveats here. All I need to assume is that there is some plausible bridge principle in the vicinity of this naive one, and this is not so implausible. See Hawthorne (2004) for a nice contemporary discussion (and defense) of deductive closure principles in epistemology.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

In Figure 1, our agent learns a posteriori that (E) a card drawn at random from a standard deck is the ace of spades, and they know a priori that E entails (H) that the card is a spade. So, the agent may (ceteris paribus) be said to know that H on the basis of E. The important thing to note here is that *we may ignore the stochastic properties of the process that generated E*. It does not matter whether our typical model of random card draws is a correct model of the process that generated E—because the agent knows that E *entails* H in this case, the agent will know H on the basis of E here *independently* of such considerations. Carnap wanted the same kind of independence to obtain in the case of inductive-logical bridge principles. In other words, he wanted the inductive-logical picture to look as simple as our Figure 1. As I have implied above, I think *that* dream of Carnap's cannot be achieved. I think things just are not so tidy in the case of inductive-logical bridge principles. That is, I think that it is all but hopeless to have anything like the sort of bridge principle Carnap wanted (as stated above) for confirmation *as firmness* and *credence*. I am skeptical here (mainly) for two reasons. First, I do not know what it *means* for an agent to know *E and nothing else* (a posteriori).[14] Second, such a principle would seem to require the existence of objective, a priori probabilities, and I do not think that there are such things. That's the bad news. The good news is that I think that we can avoid these problems when it comes to bridging confirmation as *increase in firmness* and *evidential support*. I will argue that bridging *these* concepts does *not* require *either* a "and the agent knows nothing else a posteriori" clause *or* the existence of objective a priori probabilities. But, some additional complexity is required in the inductive case, because in the inductive case *the nature of the stochastic process that generates E cannot be ignored.*

Again, it helps to picture the sort of case I have in mind. Figure 2 depicts an agent who learns a posteriori that (E) a card drawn at random from a standard deck is either a 10 or a jack, and they know a priori that—*in the standard probability model $\mathcal{M}$ used to model random card draws—E* is *positively correlated* with the proposition that (H) the card is a face card.

I submit that in such cases the agent knows (ceteris paribus)[15] that E *evidentially supports H—provided that the agent also knows that the model*

14. Indeed, one might reasonably wonder how it is even *possible* for E to be the agent's *only* a posteriori knowledge, when their knowledge is supposed to be closed under logical consequence in accordance with the deductive bridge principle that Carnap himself endorsed.

15. As in the deductive case, there are bound to be caveats required to make this bridge principle plausible. I will not try to articulate any of these here. This is a task for a longer treatise on inductive logic (I hope to articulate these in my book on inductive logic).

https://doi.org/10.1086/518320 Published online by Cambridge University Press

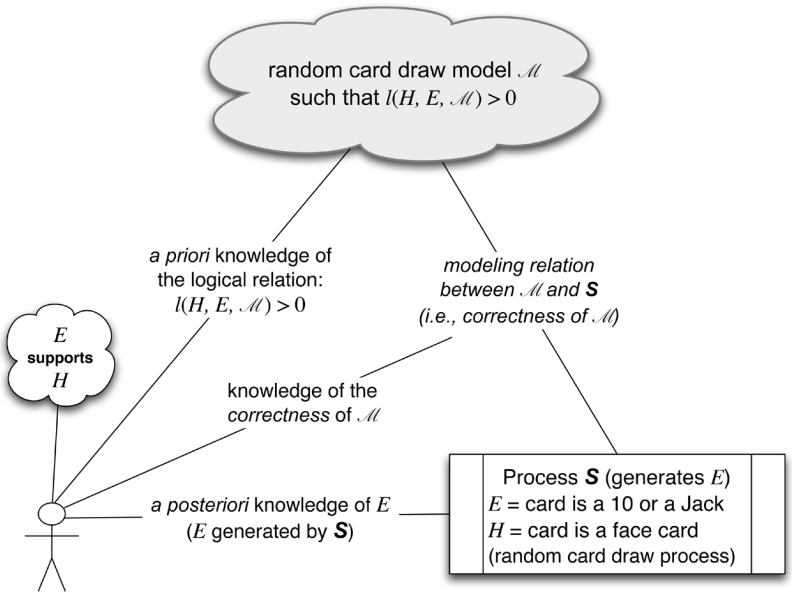

Figure 2. Qualitative confirmation and evidential support.

$\mathcal{M}$ is a correct model of the stochastic process $\mathcal{S}$ that generated the event E. That is, I am suggesting the following bridge principle (or inference rule) relating *confirmation as increase in firmness* and *evidential support*:

> *a* knows (a posteriori) that E by observing the outcome of a stochastic process $\mathcal{S}$.
> *a* knows (a priori) that E confirms (increase in firmness sense) H *in the model* $\mathcal{M}$.
> *a* knows (a posteriori) that $\mathcal{M}$ is a *correct* model of the stochastic process $\mathcal{S}$.[16]
> $\therefore$ *a* knows that E evidentially supports H.

16. A fair amount of metaphysical and epistemological work needs to go into this step. First, we need to say what it *means* for a probability model to be *correct* concerning a stochastic process, and second we need to say how we could come to *know* this. Presumably, the former would involve a story about the metaphysics of stochastic processes, and the latter would involve a delicate story about the epistemology of probability (delicate because there is the threat of a regress here, if we are inclined to be *evidentialists* about the knowledge of model correctness itself). I will bracket these issues here, since this article is mainly concerned with formulating prima facie plausible inductive-logical bridge principles, not providing a complete story about probabilistic metaphysics and epistemology.

https://doi.org/10.1086/518320 Published online by Cambridge University Press

I think that there are lots of examples illustrating the plausibility of the bridge principle stated above (and implicitly pictured in Figure 2).[17] For instance, when a pregnancy test ($\mathcal{S}$) that is known to be reliable is administered (properly, and on an appropriate individual, etc.), the observation of a positive test result (E) constitutes evidence in favor of pregnancy (H). This sort of example fits the mold of our bridge principle perfectly. In such cases, the observation is of E, an event generated by a stochastic process $\mathcal{S}$, and in the probability model $\mathcal{M}$ of $\mathcal{S}$, which we know (let us assume) to be correct, there is a large positive likelihood ratio $l(H, E, \mathcal{M})$. Such cases are canonical ones in which we are inclined to infer that E constitutes strong evidence in favor of H. Indeed, these are precisely the kinds of cases that statisticians use to illustrate how we should interpret the evidential import of the outcomes of stochastic processes (Royall 1997). As such, whereas Carnap was trying to provide a logical foundation for *credence* (or subjective *probability*), we can now be seen to be aiming for a logical foundation for *evidential support*.

Finally, I would like to say something about the prospects of formulating bridge principles relating *comparative confirmation* (as increase in firmness) and *comparative evidential support*. This case is more controversial, because the content of any such principle will depend sensitively on the *ordinal structure* of one's particular measure of confirmation. And, there is widespread ordinal (or comparative) disagreement between such measures (Fitelson 2001). Nonetheless, I think such principles can be formulated. Figure 3 illustrates how I think such principles would work.

In this example, our agent learns a posteriori that (E) a card drawn at random from a standard deck is an ace, and they know a priori that—*in the standard probability model $\mathcal{M}$ used to model random card draws*—$l(H_1, E, \mathcal{M}) > l(H_2, E, \mathcal{M})$, where H_1 is the hypothesis that the card is either the ace of spades or the ace of diamonds, and H_2 is the hypothesis that

17. Most of these involve cases where the notion of "evidential support" is of an *externalist* nature. I think that this bridge principle is harder to defend from an *internalist* point of view in epistemology. As such, traditional Bayesian confirmation theorists who tend to assume that all confirmation judgments *supervene* on some agent's credence function (*internalism* about evidential support) may not always be happy with my examples. As far as I can see, this is bad news for traditional Bayesian confirmation theory, since these examples—even the ones that cannot be given an internalist gloss—seem compelling to me. Besides, I think that the problem of old evidence has already showed us that this supervenience assumption implicit in traditional Bayesian confirmation theory is false. That can be seen with reference to my pregnancy test example by thinking about cases in which the agent already knows that the outcome of the test was positive. To my mind, this is *irrelevant* to whether E evidentially supports H. Intuitively, E supports H here *whether or not E is already known to have occurred*. It seems that this directs us toward an externalist notion of evidence, and I am perfectly happy with that (as are most statisticians, I would say!).

https://doi.org/10.1086/518320 Published online by Cambridge University Press

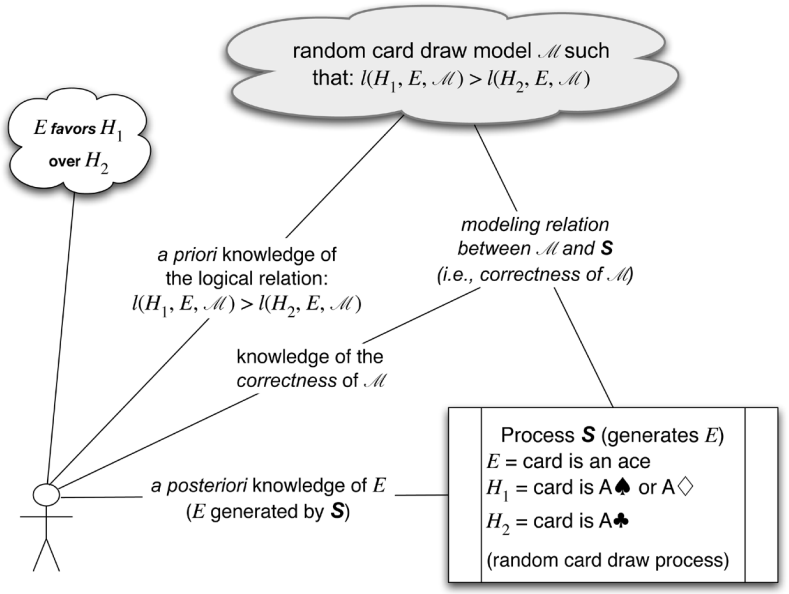

Figure 3. Comparative confirmation and favoring.

the card is the ace of clubs. I submit that in such cases the agent knows (ceteris paribus) that E *favors* H_1 *over* H_2. That is, the agent may infer in such cases that E constitutes better evidence for the truth of H_1 than for the truth of H_2. I have intentionally chosen an example here in which there are other measures of confirmation as increase in firmness that disagree with l on this comparative claim. For instance, if we follow Milne (1996) and use the ratio measure $r(H, E, \mathcal{M}) = [\Pr_{\mathcal{M}}(H|E)]/[\Pr_{\mathcal{M}}(H)]$, then we get $r(H_1, E, \mathcal{M}) = r(H_2, E, \mathcal{M})$ in this example, which would *not* undergird the inference that E favors H_1 over H_2. This sort of example reflects a long-standing controversy over alternative probabilistic accounts of comparative (or relational) confirmation (and support). I do not have the space here to expand on this controversy, but I have written extensively on this topic elsewhere (Fitelson 2007).

5. Conclusion. Carnap tried to provide an inductive-logical foundation for (epistemic) *probability*. I have explained what I think the shortcomings of his project were. Mainly, these involved problems with simultaneously satisfying three Carnapian desiderata for inductive logic, which I have called analyticity, logicality, and applicability. I then explained how one can overcome these difficulties by opting for an inductive-logical foundation for a

https://doi.org/10.1086/518320 Published online by Cambridge University Press

different epistemic concept: *evidential support*. I briefly sketched my favored theory of inductive logic (in this sense), and I explained how it can simultaneously satisfy all three of our Carnapian desiderata for inductive logic. Moreover, I argued that the resulting framework is widely and intuitively applicable to the interpretation of statistical evidence. I have provided only a broad sketch of how I think this new approach to inductive logic should work. I plan to produce a fuller treatment in a future monograph.
