Time-Varying Beta and the Value Premium

Hui Guo, Chaojiang Wu, and Yan Yu*

Abstract

We model conditional market beta and alpha as flexible functions of state variables identified via a formal variable-selection procedure. In the post-1963 sample, the beta of the value premium comoves strongly with unemployment, inflation, and the price–earnings ratio in a countercyclical manner. We also uncover a novel nonlinear dependence of alpha on business conditions: It falls sharply and even becomes negative during severe economic downturns but is positive and flat otherwise. The conditional capital asset pricing model (CAPM) performs better than the unconditional CAPM, but this does not fully explain the value premium. Our findings are consistent with a conditional CAPM with rare disasters.

I. Introduction

In the post-1963 sample, value stocks have a smaller market beta but higher average returns than do growth stocks. An important risk-based explanation is that the value premium (the return difference between value and growth stocks) is riskier during business recessions, when the conditional equity premium is high, than during business expansions, when the conditional equity premium is low (e.g., Lettau and Ludvigson (2001), Zhang (2005)). Existing empirical evidence that the value premium has a countercyclical market beta is, however, inconclusive (e.g., Ang and Kristensen (2012)). We shed new light on this issue using a novel statistical model that allows us to tackle two possible misspecifications in previous studies.

First, earlier authors assume that the conditional beta and alpha are *linear* functions of state variables, although such a relation may be more complex, as Bai, Hou, Kung, and Zhang (2015) highlight in their investment-based model with rare disasters. Extant studies provide little empirical evidence on this potentially restrictive assumption, due to the lack of an appropriate statistical method. We

fill the gap by proposing a single-index varying-coefficient setup. Our empirical model allows for a flexible, data-determined functional dependence of the conditional beta and alpha on an index that is a linear function of some state variables. The single-index varying-coefficient model nests previous linear models as a special case.

Second, only time-series variation in market beta that comoves with conditional equity premium and variance drives a wedge between the unconditional and the conditional capital asset pricing model (CAPM). Earlier authors use standard stock market return and variance predictors as state variables. This approach is potentially problematic because Welch and Goyal (2008) and Paye (2012) have shown that many of these variables have rather weak predictive power for stock market returns and stock market variance, respectively. In addition, Ghysels (1998), Harvey (2001), and Cooper and Gubellini (2011) have cautioned that the estimation of conditional factor models can be sensitive to the choice of state variables. To address these issues, we identify the most relevant state variables from a comprehensive pool via a formal exhaustive variable-selection procedure. Investment-based models (e.g., Zhang (2005)) stress a direct link between the conditional beta and business fluctuations. To investigate this conjecture, we include closely watched gauges of aggregate economic activity as candidate state variables, in addition to commonly used stock market return and variance predictors.

The single-index modeling is a popular nonparametric approach that alleviates the curse of dimensionality (e.g., Carroll, Fan, Gijbels, and Wand (1997), Yu and Ruppert (2002)). It is a natural fit of our empirical specification. We can think of the single index as a composite measure of business conditions that are the main driver of the conditional equity premium and variance in risk-based asset pricing models. When the conditional beta is a monotonic function of the single index, the interpretation of the single-index coefficients is similar to that for linear models. That is, we can test the hypothesis that the conditional beta changes countercyclically across time by simply inspecting the signs of the single-index coefficients. We make several novel extensions to the existing single-index varying-coefficient model (Xia and Li (1999), Fan, Yao, and Cai (2003)) when using it to estimate and test the conditional CAPM. First, to account for heteroskedasticity in stock returns, we model the conditional volatility as a flexible function of the single index. Second, to facilitate the exhaustive variable-selection procedure, we develop a computationally expedient iterative fixed-point algorithm using penalized splines for estimation. Last, we derive asymptotic distributions for test statistics of the conditional CAPM.

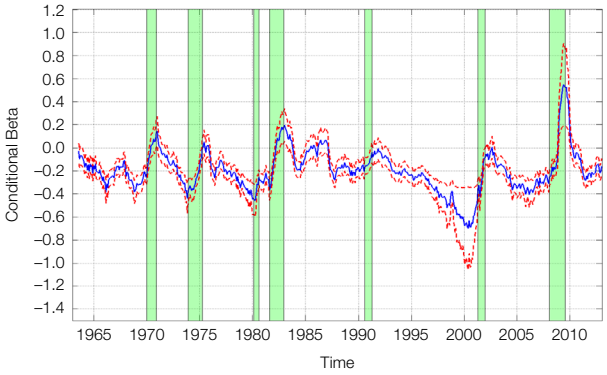

We document strong countercyclical variation in the value premium's market beta over the July 1963–Dec. 2012 period. The unemployment rate and the inflation rate, the two macroeconomic variables most closely monitored by the Federal Reserve, are selected as the state variables for the conditional beta. Moreover, the conditional beta correlates negatively with the procyclical inflation rate and correlates positively with the countercyclical unemployment rate. To the best of our knowledge, the finding of a close relation between the value premium's conditional beta and key aggregate economic activity measures is novel. Among commonly used stock market return predictors, the price–earnings ratio is

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

identified as a significant state variable. Again, the conditional beta correlates negatively with the procyclical price–earnings ratio. In Figure 1, we plot the fitted conditional beta, with shaded areas indicating business recessions dated by the National Bureau of Economic Research (NBER). Consistent with risk-based explanations, it increases sharply during business recessions and decreases during business expansions. The countercyclical beta helps explain the value premium. The alpha is 5.6% per annum for the unconditional CAPM, whereas it decreases by more than 20%, to 4.4% per annum, for the conditional CAPM. For comparison, the alpha is 5.3% per annum when using standard predictors, that is, the dividend yield, the default premium, the term premium, and the risk-free rate, as the conditioning variables. The conditional CAPM, however, also does not fully account for the value premium; its alpha is statistically significant at the 1% level.

FIGURE 1
Conditional Beta over the July 1963–Dec. 2012 Period

Figure 1 plots monthly estimates of the value premium's conditional beta (solid line) along with its 95% confidence intervals (dashed lines). The conditioning variables are inflation, the price–earnings ratio, and unemployment, which we identify via an exhaustive variable-selection procedure. Shaded areas indicate National Bureau of Economic Research (NBER) recession periods.

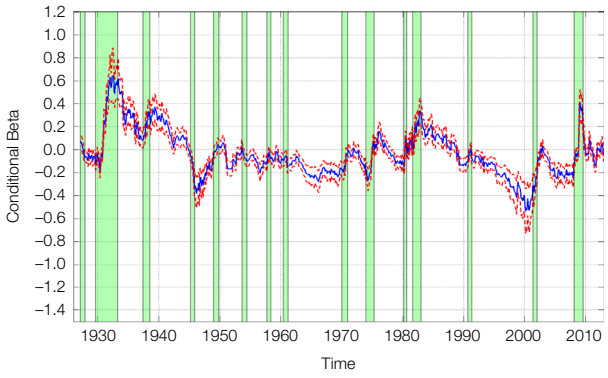

The conditional CAPM fails to fully explain the value premium, possibly because we omit some important state variables. To address partially this underconditioning bias, we follow advice of Boguth, Carlson, Fisher, and Simutin (2011) and include the value premium's lagged realized market beta as a candidate state variable. The variable-selection procedure identifies the lagged realized beta as a significant conditioning variable in the conditional CAPM for the value premium. The realized beta, however, does not subsume the information content of the financial and macroeconomic variables that we consider. Specifically, the inflation rate and the price–earnings ratio remain significant conditioning variables. Again, we find that i) the value premium's conditional beta changes countercyclically across time, and ii) the conditional CAPM does not fully explain the value premium.

Our main results are qualitatively similar for the full sample spanning the Jan. 1927–Dec. 2012 period. Figure 2 shows that the value premium's conditional beta increases during business recessions and decreases during business expansions. Campbell and Vuolteenaho (2004) and others find that the unconditional CAPM

FIGURE 2
Conditional Beta over the Jan. 1927–Dec. 2012 Period

Figure 2 plots monthly estimates of the value premium's conditional beta (solid line) along with its 95% confidence intervals (dashed lines). The conditioning variables are the default premium, industrial production, inflation, the price–earnings ratio, and the term premium, which we identify via an exhaustive variable-selection procedure. Shaded areas indicate National Bureau of Economic Research (NBER) recession periods.

explains the value premium over the Jan. 1929–June 1963 period. Figure 2 shows that the value premium's market beta increased drastically during the Great Depression. This result suggests that the CAPM explains the value premium in the pre-1963 period, possibly because, as Bai et al. (2015) point out, the rare disaster risk that accounts for a substantial portion of the value premium materialized during the Great Depression.

Wang (2003) adopts a fully nonparametric model and uncovers a nonlinear dependence of the conditional beta on prespecified state variables. In contrast, using a single-index model that is less susceptible to the curse of dimensionality and allows for variable selection and time-varying volatility, we fail to reject the null hypothesis that the value premium's conditional beta is a linear function of the selected state variables. Interestingly, however, there is novel evidence that the conditional alpha depends nonlinearly on the single index. Figure 3 shows that it falls sharply and even becomes negative during severe business downturns but is significantly positive and essentially flat otherwise. Ang and Kristensen (2012) use daily data to estimate the conditional CAPM in which the conditional beta is a nonparametric function of calendar time. In contrast with our study, Ang and Kristensen do not find countercyclical variation in the value premium's conditional beta.

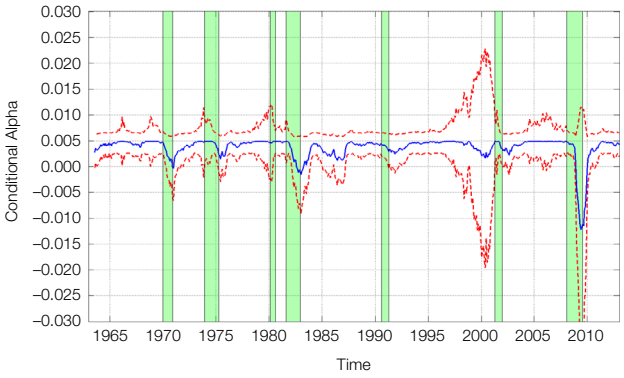

Our novel evidence of a strong correlation of the conditional beta with key aggregate economic activity gauges suggests that investment-based models remain a viable explanation of the value premium. Bai et al. (2015) propose such a model in which the conditional CAPM fails to explain the value premium in small samples because investors face rare disaster risk. The observed nonlinear dependence of the conditional alpha on business cycles is also a salient feature of their model.

The remainder of the paper proceeds as follows: We first explain the statistical methodology in Section II. We then discuss data in Section III. We present

empirical findings in Section IV. We offer some concluding remarks in Section V. Some technical materials can be found in the Appendices.

II. Statistical Methodology

We propose a novel single-index varying-coefficient model for the conditional CAPM:

$$R_{t+1} = \alpha(\mathbf{z}_t\boldsymbol{\gamma}) + \beta(\mathbf{z}_t\boldsymbol{\gamma})R_{m,t+1} + \sigma(\mathbf{z}_t\boldsymbol{\gamma})\epsilon_{t+1}, \quad t = 1,\ldots,n, \tag{1}$$

where $\{R_{t+1}\}_{t=1}^n$ and $\{R_{m,t+1}\}_{t=1}^n$ denote, respectively, the series of the value premium and the excess stock market return observed at n time points. The conditional alpha $\alpha(\cdot)$ and the conditional beta $\beta(\cdot)$ are flexible functions of the so-called single index $\mathbf{z}_t\boldsymbol{\gamma}$, which is a linear function of d-dimensional state variables $\mathbf{z}_t$, $\boldsymbol{\gamma}$ being the vector of single-index parameters. For identifiability, $\|\boldsymbol{\gamma}\| = 1$, and its first nonzero element is positive. ϵ_{t+1} is the error term, with zero mean and unit variance. The conditional volatility $\sigma(\mathbf{z}_t\boldsymbol{\gamma})$ is also a flexible function of the single index. ϵ_{t+1} is independent of $\mathbf{z}_s$ and $R_{m,s+1}$ for $s \le t$, and ϵ_{t+1} is independent of $\epsilon_{t'+1}$ for $t' \neq t$. The single-index varying-coefficient model nests the previous linear models, for example, Petkova and Zhang's (2005), as special cases, and we develop new statistical tests for the functional form of alpha and beta, that is, whether they are constant, linear, or nonlinear.

Compared with the fully nonparametric specification in which $\alpha(\cdot)$, $\beta(\cdot)$, and $\sigma(\cdot)$ are fully nonparametric functions of d-dimensional state variable vector $\mathbf{z}_t$, the model in equation (1) has two distinct advantages. First, single-index modeling overcomes the "curse of dimensionality" by projecting the d-dimensional state space to the one-dimensional single index. This advantage is especially important for our empirical investigation because we consider a moderately large number of state variables for a relatively short sample. Second, the single-index specification

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

is consistent with our maintained hypothesis that the value premium's market beta comoves with business cycles. Specifically, we can think of the single index as a composite measure of business conditions, which, as Zhang (2005) and others show in their theoretical models, are the main driver of the value premium's conditional beta.

We develop a new estimation method by combining (natural) log penalized splines, or P-splines, and a fixed-point algorithm. P-splines (e.g., Ruppert, Wand, and Carroll (2003), Jarrow, Ruppert, and Yu (2004)) are used to estimate the unknown coefficient functions $\alpha(\cdot)$ and $\beta(\cdot)$, and log P-splines are used to estimate the nonnegative volatility function $\sigma(\cdot)$. The fixed-point algorithm of Cui, Härdle, and Zhu (2011) is adapted to estimate the single-index parameters. In our experience, the fixed-point algorithm based on P-splines is computationally fast and statistically robust for the estimation of the unknown flexible functions and single-index parameters. These properties are especially desirable when we conduct an exhaustive search from a comprehensive pool to identify the most relevant state variables for modeling the conditional beta.[1]

A. P-Spline Estimation

The varying coefficients $\alpha(u)$ and $\beta(u)$ are both univariate flexible functions of the single index $u = \mathbf{z}\boldsymbol{\gamma}$ and can be estimated using P-splines. To impose the constraint of positive volatility, we estimate the volatility function $\sigma(u)$ using log P-splines, that is, the logarithmic transformation of the volatility function is modeled using P-splines (e.g., Yu, Yu, Wang, and Li (2009)). We illustrate P-splines using the truncated power basis for its easy interpretation. Other bases, such as B-splines, can be similarly adopted. The truncated power basis of degree p, with knots at $v_1, \ldots, v_k$, is $\mathbf{B}(u) = (1, u, u^2, \ldots, u^p, (u - v_1)_+^p, \ldots, (u - v_k)_+^p)$, where $(u - v_k)_+^p$ equals $(u - v_k)^p$ if $u \geq v_k$, and 0 otherwise. Any function with $p - 1$ continuous derivatives can be approximated by

$$\delta_0 + \delta_1 u + \delta_2 u^2 + \cdots + \delta_p u^p + \delta_{p+1}(u - v_1)_+^p + \cdots + \delta_{p+k}(u - v_k)_+^p \quad = \quad \mathbf{B}\boldsymbol{\delta},$$

where $\boldsymbol{\delta} = (\delta_0, \delta_1, \ldots, \delta_{p+k})^\mathsf{T}$ is the spline coefficient vector.

Denote the bases $\mathbf{B}_a$ and $\mathbf{B}_b$ and the spline coefficient vectors $\boldsymbol{\delta}_a$ and $\boldsymbol{\delta}_b$ for conditional alpha and beta, respectively. Then at u_t the conditional alpha is $\alpha(u_t) = \mathbf{B}_{a,t}\boldsymbol{\delta}_a$, and the conditional beta is $\beta(u_t) = \mathbf{B}_{b,t}\boldsymbol{\delta}_b$. Combining the scalar 1 and $R_{m,t+1}$ with the spline bases, we can write the tth row of the "design" matrix $\mathbf{X}$ as $\mathbf{X}_t = (\mathbf{B}_{a,t}, \mathbf{B}_{b,t} R_{m,t+1})$. Define the spline coefficient parameters as $\boldsymbol{\delta}_1 = (\boldsymbol{\delta}_a^\mathsf{T}, \boldsymbol{\delta}_b^\mathsf{T})^\mathsf{T}$. Then we can write the mean function of R_{t+1} $(t = 1, 2, \ldots, n)$ as

$$m_t \quad \equiv \quad E(R_{t+1}) = \mathbf{B}_{a,t}\boldsymbol{\delta}_a + \mathbf{B}_{b,t} R_{m,t+1}\boldsymbol{\delta}_b = \mathbf{X}_t\boldsymbol{\delta}_1.$$

Similarly, we approximate the volatility function using $\log\sigma(u_t) = \mathbf{B}_2(u_t)\boldsymbol{\delta}_2$, or equivalently, $\sigma(u_t) = \exp\{\mathbf{B}_2(u_t)\boldsymbol{\delta}_2\}$. Then the penalized negative log-likelihood

[1] For d candidate state variables, the number of all possible combinations is 2^d, given that the constant term is also a possible choice. Therefore, the exhaustive search can be computationally demanding when d is relatively large.

function is

$$(2)\qquad \sum_{t=1}^{n}\Big(\exp\{-2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\}\left\{R_{t+1}-\mathbf{B}_{a,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_a-\mathbf{B}_{b,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_b R_{m,t+1}\right\}^2 + 2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\Big)+\frac{n}{2}\lambda_a\boldsymbol{\delta}_a^{\mathsf{T}}\mathbf{D}_a\boldsymbol{\delta}_a+\frac{n}{2}\lambda_b\boldsymbol{\delta}_b^{\mathsf{T}}\mathbf{D}_b\boldsymbol{\delta}_b+\frac{n}{2}\lambda_2\boldsymbol{\delta}_2^{\mathsf{T}}\mathbf{D}_2\boldsymbol{\delta}_2,$$

where $\lambda_a>0$, $\lambda_b>0$, and $\lambda_2>0$ are penalty or smoothing parameters for varying coefficient functions and the volatility function, respectively; and $\mathbf{D}_\xi$ $(\xi=a,b,2)$ is a 0–1 diagonal matrix such that $\boldsymbol{\delta}_\xi^{\mathsf{T}}\mathbf{D}_\xi\boldsymbol{\delta}_\xi=\sum_{j=1}^{k_\xi}\delta_{p_\xi+j}^2$, where p_ξ and $k_\xi+j$ are the polynomial degree and the number of knots of the splines, respectively.[2] For notational convenience, we reserve subscript 1 for the mean and 2 for the volatility, unless otherwise indicated.

An appealing feature of P-splines is that the number and locations of knots are no longer crucial, and the smoothness can easily be controlled by the smoothing parameter λ through a roughness penalty term (e.g., Ruppert (2002), Ruppert et al. (2003)). We use a quadratic spline with knots placed at the equidistant quantiles of the index value. The previous P-spline estimation also allows different degrees of smoothness by using separate smoothing parameters.

One could optimize the penalized log-likelihood function in equation (2) with respect to the model parameters $\boldsymbol{\theta}=(\boldsymbol{\gamma}^{\mathsf{T}},\boldsymbol{\delta}_a^{\mathsf{T}},\boldsymbol{\delta}_b^{\mathsf{T}},\boldsymbol{\delta}_2^{\mathsf{T}})^{\mathsf{T}}$ in one step. However, the number of parameters could be large, and the estimation algorithm may not be efficient. Instead, we propose a 2-step algorithm that reweighs the mean function using the estimates of volatility function, in a fashion similar to weighted least squares. We first estimate the mean function and then use it to calculate the volatility. Parameters in the mean function are thereafter recalculated using weighted least squares, where the weights are the inverse of the estimated volatility. The 2 steps can be iterated a few times. We find that 2 or 3 iterations are usually adequate.[3] The 2-step estimation procedure is described as follows.

Step 1. Mean Function Estimation

The mean function can be estimated by minimizing

$$(3)\qquad \sum_{t=1}^{n}\left\{R_{t+1}-\mathbf{B}_{a,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_a-\mathbf{B}_{b,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_b R_{m,t+1}\right\}^2+\frac{n}{2}\boldsymbol{\lambda}_1\boldsymbol{\delta}_1^{\mathsf{T}}\mathbf{D}_1\boldsymbol{\delta}_1.$$

Given the single index $u=\mathbf{z}\boldsymbol{\gamma}$ and the design matrix $\mathbf{X}$ defined before, the spline coefficients can be obtained by a linear shrinkage estimator $\widehat{\boldsymbol{\delta}}_1=(\mathbf{X}^{\mathsf{T}}\mathbf{X}+n\boldsymbol{\lambda}_1\mathbf{D}_1)^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{R}$, where $\boldsymbol{\lambda}_1=\text{blockdiag}(\boldsymbol{\lambda}_a,\boldsymbol{\lambda}_b)=\text{diag}(\lambda_a,\ldots,\lambda_a,\lambda_b,\ldots,\lambda_b)$ is the penalty parameter matrix, $\mathbf{D}_1=\text{blockdiag}\{\mathbf{D}_a,\mathbf{D}_b\}$, and $\mathbf{R}=(R_2,\ldots,R_{n+1})^{\mathsf{T}}$ is the vector of value premiums. The estimated value premium is $\widehat{\mathbf{R}}=\mathbf{X}\widehat{\boldsymbol{\delta}}_1=\mathbf{H}\mathbf{R}$, where $\mathbf{H}=\mathbf{X}(\mathbf{X}^{\mathsf{T}}\mathbf{X}+n\boldsymbol{\lambda}_1\mathbf{D}_1)^{-1}\mathbf{X}^{\mathsf{T}}$ is the smoothing matrix.

[2] As noted by Carroll et al. (1997), this specification may also apply to quasi-likelihood models, where only the relationship between the model mean and the model variance is specified, by replacing the conditional log-likelihood function with a quasi-likelihood function.

[3] Similar treatments of iteratively estimating mean and volatility are given by Carroll, Wu, and Ruppert (1988) and Yu et al. (2009).

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

Step 2. Volatility Function Estimation and Reweighting

The volatility coefficient parameter $\boldsymbol{\delta}_2$ can be estimated by minimizing the penalized negative log-likelihood

$$(4) \quad \sum_{t=1}^{n}\left(\left\{R_{t+1}-\mathbf{X}_t\widehat{\boldsymbol{\delta}}_1\right\}^2\exp\{-2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\}+2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\right)+\frac{n}{2}\boldsymbol{\lambda}_2\boldsymbol{\delta}_2^{\mathsf{T}}\mathbf{D}_2\boldsymbol{\delta}_2,$$

where $R_{t+1}-\mathbf{X}_t\widehat{\boldsymbol{\delta}}_1\approx\sigma(\mathbf{z}_t\boldsymbol{\gamma})\epsilon_{t+1}$ is the residual from the estimation of the mean function. The volatility function is approximated using

$$(5) \quad \widehat{\sigma}(\mathbf{z}_t\boldsymbol{\gamma}) \quad = \quad \exp\left\{\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\widehat{\boldsymbol{\delta}}_2\right\}.$$

The new estimator $\widehat{\boldsymbol{\delta}}_1$ of the mean can be obtained through (penalized) weighted least squares, where the weight is the inverse of the estimated squared volatility. More specifically, the new estimator $\widehat{\boldsymbol{\delta}}_1$ minimizes the penalized weighted least squares

$$\sum_{t=1}^{n}\frac{1}{\widehat{\sigma}^2(\mathbf{z}_t\boldsymbol{\gamma})}(R_{t+1}-\mathbf{X}_t\boldsymbol{\delta}_1)^2+\frac{n}{2}\boldsymbol{\lambda}_1\boldsymbol{\delta}_1^{\mathsf{T}}\mathbf{D}_1\boldsymbol{\delta}_1.$$

It has an analytical solution $\widehat{\boldsymbol{\delta}}_1=(\mathbf{X}^{\mathsf{T}}\mathbf{W}\mathbf{X}+n\boldsymbol{\lambda}_1\mathbf{D})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{W}\mathbf{R}$, where $\mathbf{W}=\text{diag}\{1/\widehat{\sigma}^2(\mathbf{z}_t\boldsymbol{\gamma})\}$ is a diagonal weight matrix with each diagonal element calculated by equation (5). In the case of homoskedasticity, the weighting procedure is unnecessary. That is, the second step and the reweighting can be omitted altogether.

B. Smoothing Parameter Selection

The selection of smoothing parameters is crucial in any nonparametric estimation. The most common criteria used to select smoothing parameters are cross validation (CV), generalized cross validation (GCV), Mallow's C_p, Akaike's information criterion (AIC), (Akaike (1974)), and some other variations. We use GCV, which is particularly popular in the P-splines approach. In this paper, the smoothing parameter $\boldsymbol{\lambda}_1$ of the mean minimizes the GCV criterion

$$\text{GCV}(\boldsymbol{\lambda}_1) \quad = \quad \frac{\sum_{t=1}^{n}(R_{t+1}-\mathbf{X}_t\boldsymbol{\delta}_1)^2}{n\{1-n^{-1}\text{tr}(\mathbf{H})\}^2},$$

where tr($\mathbf{H}$) is the trace of the smoothing matrix and is often called the "effective" degrees of freedom of the fit (see Hastie and Tibshirani (1990)). Similarly, the smoothing parameter λ_2 of volatility minimizes the GCV criterion

$$\text{GCV}(\lambda_2) \quad = \quad \frac{\text{deviance}(\lambda_2)}{n\left\{1-n^{-1}\text{tr}\left(\mathbf{B}_2(\mathbf{B}_2^{\mathsf{T}}\mathbf{B}_2+n\lambda_2\mathbf{D}_2)^{-1}\mathbf{B}_2^{\mathsf{T}}\right)\right\}^2},$$

where the numerator is the deviance of the model for a given value of λ_2. The optimal smoothing parameter is often selected through a grid search. For the 2-dimensional $\boldsymbol{\lambda}_1$, to effectively find the optimal amount of smoothing, we recommend a straightforward grid-searching scheme. First we constrain the two smoothing parameters to be the same and conduct a 1-dimensional grid search to find the

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

optimal smoothing parameter. Then we fix 1 smoothing parameter at the value obtained from the previous grid search and conduct a grid search for the other parameter. We have studied 2-dimensional separate smoothing parameters and found no significant improvement in the fit using separate smoothing parameters. Therefore, we present our results using a single smoothing parameter in this paper when estimating the mean functions.

C. A Fixed-Point Algorithm

The objective functions in expressions (2) and (3) are nonlinear in the single-index parameters $\boldsymbol{\gamma}$, and we need to estimate them using numerical methods. We do not use standard nonlinear optimization routines, for example, *lsqnonlin* and *fminunc* from MATLAB and *nls* from S-PLUS, because for high-dimensional $\boldsymbol{\gamma}$, the convergence of the estimates may be slow, and the resulting estimates may be very sensitive to starting values. Instead, we develop a fixed-point algorithm. Cui et al. (2011) propose the fixed-point algorithm for local linear estimation for single-index models using an estimating function approach because it works well for high-dimensional single-index models. In this paper, we adapt the algorithm to P-spline estimation for our single-index varying-coefficient models. In our implementation, the fixed-point algorithm enables us to obtain efficient single-index parameter estimates of $\boldsymbol{\gamma}$ in equation (3) by using a series of equations for its first derivatives through an iterative procedure. Compared with the aforementioned nonlinear optimization routines, our fixed-point algorithm is less sensitive to starting values and works better for high-dimensional $\boldsymbol{\gamma}$. The details of the fixed-point algorithm, as well as the estimation algorithm, can be found in Appendix A.

D. Variable-Selection Procedure

Few studies have addressed variable selection for single-index varying-coefficient models. In a noticeable exception, Fan et al. (2003) use backward stepwise deletion in combination with the modified t-statistic and the AIC for variable selection. This heuristic procedure, however, does not guarantee a global solution for the best subset variables. To address this concern, we use some criterion to choose the best model from all possible combinations of candidate state variables. The exhaustive search approach can be computationally intensive and time-consuming. This drawback is not a serious concern for our study. Although we consider a quite comprehensive set of candidate state variables, the number of all possible combinations is still manageable. Moreover, as mentioned previously, P-splines and the fixed-point algorithm allow for expedient computation.

The AIC and the Bayesian information criterion (BIC) (Schwarz (1978)) are the most popular likelihood-based information criteria for variable selection. Both criteria attempt to balance goodness of fit and the simplicity of the model. We use BIC, which tends to select more parsimonious models. BIC in our model is defined as

$$\sum_{t=1}^{n}\Big(\exp\{-2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\}\left\{R_{t+1}-\mathbf{B}_{a,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_a-\mathbf{B}_{b,t}(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_b R_{m,t+1}\right\}^2 + 2\mathbf{B}_2(\mathbf{z}_t\boldsymbol{\gamma})\boldsymbol{\delta}_2\Big)+\log(n)\mathrm{df},$$

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

where the first term is the negative-two log-likelihood function of the model, and df is the model effective degrees of freedom.[4]

E. Tests of Alpha and Beta

To test whether conditional alpha or beta is constant, linear, or nonlinear, we first establish consistency and asymptotic normality and then construct the Wald statistic for inferences. There are two types of asymptotics for P-splines: Fixed and increasing number of knots. We use fixed-knot asymptotics because they are most practical and relevant in empirical applications (Yu and Ruppert (2002), Jarrow et al. (2004)). In addition, the bias due to fixed-knot approximation of P-splines of smooth functions is negligible compared with the standard deviation of the function estimates and the bias due to penalty. The asymptotics introduced here are similar in spirit to Theorem 2 of Yu and Ruppert (2002) and to Theorem 2 of Wu, Lin, and Yu (2011).

Theorem 1. Under mild regularity conditions, if the smoothing parameter $\lambda_n \sim o(n^{-1/2})$, then a sequence of estimators $\widehat{\boldsymbol{\theta}} = (\widehat{\boldsymbol{\gamma}}^{\mathsf{T}}, \widehat{\boldsymbol{\delta}}_a^{\mathsf{T}}, \widehat{\boldsymbol{\delta}}_b^{\mathsf{T}}, \widehat{\boldsymbol{\delta}}_2^{\mathsf{T}})^{\mathsf{T}}$ is root-n consistent and converges to a normal distribution

$$\sqrt{n}(\widehat{\boldsymbol{\theta}} - \boldsymbol{\theta}) \quad \xrightarrow{D} \quad \mathrm{N}(0, \mathbf{I}^{-1}(\boldsymbol{\theta})), \tag{6}$$

where $\mathbf{I}(\boldsymbol{\theta})$ is the usual Fisher information.

The proof of this theorem is similar to that noted by Yu et al. (2009). The penalty parameter is assumed to vanish fast enough as n goes to infinity to ensure that the result given in expression (6) involves no penalty parameter. For finite sample inference, asymptotic results with a fixed penalty parameter would be preferred to avoid overestimating the variance of $\boldsymbol{\theta}$, as in expression (6). Using the delta method, the sandwich formula for the covariance matrix will be given by

$$\boldsymbol{\Gamma}_n^{-1}\big(\boldsymbol{\theta}(\boldsymbol{\lambda})\big)\boldsymbol{\Lambda}_n\big(\boldsymbol{\theta}(\boldsymbol{\lambda})\big)\boldsymbol{\Gamma}_n^{-T}\big(\boldsymbol{\theta}(\boldsymbol{\lambda})\big),$$

where

$$\begin{aligned}
\boldsymbol{\Gamma}_n\big(\boldsymbol{\theta}(\boldsymbol{\lambda})\big) &= \sum_{t=1}^{n} (\partial/\partial\boldsymbol{\theta}^{\mathsf{T}})\Phi_{\mathbf{z}_t\boldsymbol{\gamma}}(\boldsymbol{\theta}), \\
\boldsymbol{\Lambda}_n\big(\boldsymbol{\theta}\big) &= \sum_{t=1}^{n} \Phi_{\mathbf{z}_t\boldsymbol{\gamma}}(\boldsymbol{\theta})\Phi_{\mathbf{z}_t\boldsymbol{\gamma}}^{\mathsf{T}}(\boldsymbol{\theta}), \\
\Phi_{\mathbf{z}_t\boldsymbol{\gamma}}(\boldsymbol{\theta}) &= -(\partial/\partial\boldsymbol{\theta}^{\mathsf{T}})l_n(\boldsymbol{\theta}; \mathbf{z}_t\boldsymbol{\gamma}) + \boldsymbol{\lambda}\mathbf{D}\boldsymbol{\theta},
\end{aligned}$$

[4]AIC assigns a smaller weight to the simplicity of the model, where $\log(n)$ is replaced by 2. As a consequence, AIC tends to select more complex models. This is confirmed in our empirical study. For example, for the monthly data spanning the July 1963–Dec. 2012 period, in addition to the unemployment rate, the inflation rate, and the price–earnings ratio selected by BIC, the dividend–price ratio is also selected by AIC as a conditioning variable in the single index. Nevertheless, the results remain qualitatively similar.

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

and $l_n(\boldsymbol{\theta}; \mathbf{z}_t\boldsymbol{\gamma})$ is the log-likelihood function (see Yu and Ruppert (2002), Yu et al. (2009)). The sandwich estimator of the covariance matrix is

$$\boldsymbol{\Omega}_n(\widehat{\boldsymbol{\theta}}(\boldsymbol{\lambda})) = \boldsymbol{\Gamma}_n^{-1}\big(\widehat{\boldsymbol{\theta}}(\boldsymbol{\lambda})\big)\boldsymbol{\Lambda}_n\big(\widehat{\boldsymbol{\theta}}(\boldsymbol{\lambda})\big)\boldsymbol{\Gamma}_n^{-T}\big(\widehat{\boldsymbol{\theta}}(\boldsymbol{\lambda})\big). \tag{7}$$

The asymptotic properties in expression (7) can be conveniently used for joint inferences concerning the spline coefficients. In general, if we are testing the null hypothesis $H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$, where $\mathbf{L}$ is an r by $\dim(\boldsymbol{\theta})$ matrix of full row rank, we construct the Wald statistic

$$W = (\mathbf{L}\widehat{\boldsymbol{\theta}} - \mathbf{c})^{\mathsf{T}}\big(\mathbf{L}\boldsymbol{\Omega}_n(\widehat{\boldsymbol{\theta}}(\boldsymbol{\lambda}))\mathbf{L}\big)^{-1}(\mathbf{L}\widehat{\boldsymbol{\theta}} - \mathbf{c}). \tag{8}$$

Under H_0, the Wald statistic W has a limiting χ^2 distribution with r degrees of freedom. In particular, hypotheses on testing conditional alpha and beta can be formulated using spline coefficients. For example, testing $H_0: \alpha \equiv 0$ is equivalent to testing the hypothesis that all its spline coefficients are zeros (i.e., $H_0: \boldsymbol{\delta}_a \equiv 0$). The null hypothesis $H_0: \beta$ *is linear in the single index* is equivalent to the hypothesis that all nonlinear spline coefficients are simultaneously 0.

The covariance matrix $\boldsymbol{\Omega}_n(\widehat{\boldsymbol{\theta}})$ in the Wald statistic in equation (8) can be difficult to calculate using the sandwich formula for finite samples. Instead, we use bootstrapping resamples to construct the covariance matrices in equation (8). Because of heteroskedasticity, we use a specialized wild bootstrap procedure. The wild bootstrap procedure, originally proposed by Wu (1986) and extended by Mammen (1993) and others, is particularly useful in the presence of heteroskedasticity and small sample sizes. Unlike the usual residual bootstrap, in which residuals are drawn randomly and added to the estimates to construct resamples, the wild bootstrap accounts for heteroskedasticity by creating weighted residuals, where the weight is a random variable with zero mean and unit variance. The details of the wild bootstrap procedure can be found in Appendix B.

Following Ang and Kristensen (2012), we define the long-run alpha, α_{LR}, as the average of conditional alphas:

$$\alpha_{\mathrm{LR}} \equiv \lim_{n\to\infty}\frac{1}{n}\sum_{t=1}^{n}\alpha(\mathbf{z}_t\boldsymbol{\gamma}). \tag{9}$$

The long-run alpha measures the part of the value premium that is unaccounted for by the conditional CAPM. We calculate the long-run alpha and its standard errors from the conditional alpha estimates and the wild bootstrap resamples. Note that the hypothesis of zero long-run alpha, that is, $H_0: \alpha_{\mathrm{LR}} = 0$, is not the same as the hypothesis that conditional alpha is 0 over any values of the single index. Zero conditional alpha implies zero long-run alpha; the opposite, however, is not true.

III. Data

We obtained the monthly risk-free rate, excess stock market return, and value premium data from Kenneth French (http://mba.tuck.dartmouth.edu/pages/faculty/ken.french). Following earlier studies (e.g., Ferson and Harvey (1999), Petkova and Zhang (2005)), we use standard stock market return predictors as

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

conditioning variables. The default premium (DEF) is the yield spread between Baa- and Aaa-rated corporate bonds. The term premium (TERM) is the yield spread between 10-year Treasury bonds and 3-month Treasury bills. The stochastically detrended risk-free rate (RREL) is the difference between the risk-free rate and its average in the previous 12 months. The dividend–price ratio (DP) is the dividend paid in the most recent 12 months divided by the end-of-month stock market price. The price–earnings ratio (PE) is the end-of-month stock market price divided by the earnings in the most recent 10 years. The realized stock market volatility (VOL) is the sum of the squared daily excess stock market returns in a month. We obtained these data up to 2008 from Amit Goyal (http://www.hec.unil.ch/agoyal) and updated them to 2012 using the data obtained from Kenneth French, Robert Shiller (http://www.econ.yale.edu/shiller), and the Federal Reserve Bank of St. Louis (https://fred.stlouisfed.org).

We also consider several major economic indicators as additional candidate conditioning variables. The unemployment (UE) and inflation (INF) rates are arguably the most important gauges of aggregate economic activity, because by legal mandate, the Federal Reserve is required to maintain full employment and price stability.[5] We obtain the civilian unemployment rate and the Consumer Price Index (CPI) for all urban consumers (all items) from the Federal Reserve Bank of St. Louis. We use the year-over-year log changes in the CPI to measure the inflation rate and the year-over-year log changes in the unemployment rate to measure the job market condition.[6] Chen, Roll, and Ross (1986) and others find that industrial production (IP) is a priced state variable in the cross section of stock returns. We include its year-over-year log change, obtained from the Federal Reserve Bank of St. Louis, as a conditioning variable.

Lewellen and Nagel (2006) use the realized beta ($BETA_R$) as a proxy for the conditional beta. Boguth et al. (2011) illustrate via simulation that under some mild conditions, the lagged realized beta is a good instrumental variable for the conditional beta and can substantially reduce the underconditioning bias. As a robustness check, we include the lagged realized beta as a candidate conditioning variable. Following Lewellen and Nagel (2006), we estimate the realized beta of a month by regressing the daily value premium on a constant and the daily excess market return in that month using ordinary least squares (OLS) regression.

[5]Several recent studies, for example, those by Chen and Zhang (2011), Petrosky-Nadeau, Zhang, and Kuehn (2013), and Belo, Lin, and Bazdresch (2014), have noted the important effect of labor market conditions on asset prices.

[6]Under the Taylor (1993) rule, the federal funds rate is adjusted according to the inflation rate and the deviation of the unemployment rate from its natural rate. Because there is substantial uncertainty about the natural rate of unemployment, Staiger, Stock, and Watson (1997) and Orphanides and Williams (2002), however, argue that the Fed should target changes in the unemployment rate instead of the level. In addition, Berger, Dew-Becker, Schmidt, and Takahashi (2015) suggest that the Fed targets changes in the unemployment rate because layoffs lead to substantial social welfare losses. Consistent with these arguments, Berger et al. find that the federal funds rate correlates more closely with changes in the unemployment rate than with the level of the unemployment rate. That is, changes in the unemployment rate appear to be a better measure of business conditions than does the level of the unemployment rate. Similarly, when we include both changes in and the level of the unemployment rate as candidate conditioning variables, changes are always selected by the variable-selection procedure, but the level is not.

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

Table 1 provides summary statistics of the state variables. Consistent with the conjecture that the value premium's conditional beta is countercyclical, we find that $BETA_R$, a proxy for the conditional beta, correlates positively with UE and correlates negatively with IP and INF. Conversely, except for PE and TERM, the correlation of $BETA_R$ with stock market return predictors is rather weak. Similarly, correlations between macroeconomic variables and stock market return predictors are not particularly strong. These results highlight the importance of including macroeconomic variables as candidate conditioning variables because they may provide additional information about the conditional beta beyond financial variables.

TABLE 1

Summary Statistics of Conditioning Variables

Table 1 reports descriptive statistics of conditioning variables (Panel A) and their correlation matrix (Panel B). $BETA_R$ is the value premium's realized beta. DEF is the default premium. TERM is the term premium. RREL is the stochastically detrended risk-free rate. DP is the dividend yield. IP is the industrial production. INF is inflation. VOL is the realized stock market volatility. PE is the price–earnings ratio. UE is unemployment. For comparison, we also include the National Bureau of Economic Research (NBER) business recession indicator, CYCLE. All variables are in percentage points except for $BETA_R$, PE, and CYCLE. PE has been divided by 100. The monthly sample spans the July 1963–Dec. 2012 period.

Panel A. Descriptive Statistics of Conditioning Variables

Variables	Mean	Median	Std. Dev.	Kurt	Skew	Min.	Max.

IV. Empirical Findings

Campbell and Vuolteenaho (2004), Fama and French (2006), Ang and Chen (2007), and others find that the value premium poses a challenge to the unconditional CAPM in the post-1963 sample but not in the pre-1963 sample. Following Ang and Kristensen (2012) and others, we focus mainly on the post-1963 sample in our empirical test of the conditional CAPM. Nevertheless, we show that the value premium's conditional beta changes countercyclically in both post- and pre-1963 samples.

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

A. Conditional Beta as a Function of Macroeconomic and Financial Variables

For the July 1963–Dec. 2012 period, we select the model with PE, INF, and UE as the conditioning variables via an exhaustive variable-selection procedure. The scaled stock price, such as PE, plays a prominent role in the stock market return predictability literature because of its mechanical relation with the conditional equity premium (e.g., Campbell and Shiller (1988)), as highlighted in leading asset pricing models by Campbell and Cochrane (1999) and Bansal and Yaron (2004). Lettau and Ludvigson (2001) emphasize using the scaled stock price (i.e., the consumption–wealth ratio) in estimating the conditional CAPM for the value premium, and Zhang (2005) formalizes the argument using an equilibrium model in which the value premium's conditional market beta comoves closely with the scaled stock price. By identifying PE as a significant state variable, we confirm that the scaled stock price indeed has important effects on the dynamic of the value premium's conditional market beta. Moreover, because the unemployment and inflation rates are the two gauges of aggregate economic activity most closely watched by the Federal Reserve, our results confirm a key implication of the aforementioned investment-based asset pricing models: that the value premium's conditional market beta changes with business conditions. To the best of our knowledge, this important empirical evidence for investment-based models is novel.[7]

Unlike the case for the scaled stock price, the existing literature does not provide a fully fledged theoretical explanation for the relation between the other financial variables and the conditional equity premium. Financial economists (e.g., Fama and French (1989)) usually justify the predictive power of these financial variables for stock market returns with the arguments that i) the conditional equity premium is countercyclical and ii) these financial variables have strong cyclical variation across time. For example, Stock and Watson (2003) and others show that TERM, a commonly used stock market return predictor, has strong predictive power for aggregate output and inflation. Interestingly, although TERM is a standard conditioning variable in the extant empirical studies, it is not selected in the conditional CAPM. This is because, as we show later, UE subsumes the information content of TERM about the value premium's conditional beta: The selected model has PE, INF, and TERM as the conditioning variables when we exclude UE as a candidate state variable. Our variable-selection results suggest that, consistent with investment-based models, macroeconomic variables can be more informative than can financial variables in estimating the conditional CAPM.

We report the main estimation results of the selected single-index model in Table 2. Panel A shows that the single index correlates positively with the procyclical variables INF and PE and correlates negatively with the countercyclical variable UE. Because there is a monotonically negative relation between the conditional beta and the single index (untabulated), our results indicate that the

[7] In Zhang's (2005) model, the value premium's conditional market beta depends only on the scaled stock price because of the simplifying assumption that productivity shocks correlate perfectly with pricing kernel shocks. In general cases where the assumption is relaxed, the conditional market beta should comove with both the aggregate productivity and the scaled stock price, as we document in this paper.

TABLE 2

Estimation of the Single-Index Varying-Coefficient Model

Table 2 reports the estimation results of the single-index varying-coefficient model, in which we identify the conditioning variables via an exhaustive variable-selection procedure from standard macroeconomic and financial variables. Panel A reports the single-index parameter estimates of the selected conditioning variables. INF is inflation. PE is the price–earnings ratio. UE is unemployment. Panels B, C, and D report statistical tests on the conditional beta, the conditional alpha, and the long-run alpha (α_{LR}), respectively. Tests on the conditional beta and alpha are based on the Wald statistics in equation (8). Tests on the long-run alpha are based on equation (9). All covariance matrices and standard errors (SE) (reported in parentheses) are calculated using the wild bootstrap. The monthly sample spans the July 1963–Dec. 2012 period.

Parameter (Variable)		Estimate (SE)
Panel A. Single-Index Parameter Estimates		
γ_1(INF)		0.9574 (0.0994)
γ_2(PE)		0.2524 (0.1305)
γ_3(UE)		−0.1402 (0.0872)
Hypothesis	Wald Statistic	*p*-Value
Panel B. Tests on Beta		
$H_0:\beta=0$	89.12	0.0000
$H_0:\beta=$Constant	70.10	0.0000
$H_0:\beta=$Linear	7.31	0.2926
Panel C. Tests on Alpha		
$H_0:\alpha=0$	27.22	0.0006
$H_0:\alpha=$Constant	12.76	0.0781
$H_0:\alpha=$Linear	11.09	0.0857
Hypothesis		Estimate (SE)
Panel D. Test on Long-Run Alpha		
$H_0:\alpha_{LR}=0$		0.0038 (0.0011)

conditional beta of the value premium increases with UE and decreases with INF and PE and thus changes countercyclically across time. Figure 1 illustrates this point. We observe a sharp spike in the value premium's conditional beta for each of 7 business recessions over the July 1963–Dec. 2012 period. Moreover, the conditional beta tends to decrease during business expansions. Our results reveal a strong countercyclical variation in the conditional beta of the value premium.[8]

Table 3 shows that the selected conditional variables forecast excess market returns. The 1-month-ahead excess market returns correlate positively with UE and negatively with INF and PE; both INF and PE are statistically significant at the 5% level (row 1). Similarly, for the 3-month-ahead excess market returns, their positive correlation with UE is significant at the 10% level, and their negative correlations with INF and PE are significant at the 1% level (row 5). Moreover, the estimated single index (SI) that is a linear function of UE, INF, and PE has significant predictive power for the 1-month-ahead market returns at the 5% level (row 2) and for the 3-month-ahead market returns at the 1% level (row 6). The single index correlates closely with the first principal component (PC1) of the nine

[8]In Zhang's (2005) model, value stocks are riskier than growth stocks during business recessions. Consistent with this theoretical prediction, we find that the betas of value stocks correlate negatively with INF and PE and correlate positively with UE. In contrast, the betas of growth stocks correlate positively with INF and PE and correlate negatively with UE. As a result, the betas of value stocks increase sharply during business recessions, whereas the betas of growth stocks decrease during economic downturns. For brevity, we do not report these results here, but they are available from the authors.

TABLE 3
Forecasting Excess Market Returns

Table 3 reports the ordinary least squares (OLS) regression results of forecasting excess stock market returns. INF is inflation. PE is the price–earnings ratio. UE is unemployment. SI is the single index estimated using the post-1963 sample. PC1 is the first principal component of the 9 candidate macroeconomic and financial variables. The monthly sample spans the Aug. 1963–Dec. 2012 period. Heteroskedasticity-corrected *t*-values are reported in parentheses. *, **, and *** indicate significance at the 10%, 5%, and 1% levels, respectively.

	UE	INF	PE	SI	PC1	Adj. R^2
Panel A. 1-Month-Ahead Excess Market Returns						
1	0.015 (1.235)	−0.252** (−2.463)	−0.066** (−2.175)			0.014
2				−0.159** (−2.388)		0.011
3					−0.002 (−1.451)	0.003
4				−0.156* (−1.922)	−0.001 (−0.071)	0.009
Panel B. 3-Month-Ahead Excess Market Returns						
5	0.044* (1.868)	−0.675*** (−3.991)	−0.190*** (−3.804)			0.039
6				−0.490*** (−4.530)		0.034
7					−0.005*** (−2.668)	0.014
8				−0.460*** (−3.492)	−0.009 (−0.358)	0.033

candidate conditioning variables, with a correlation coefficient of 84% (untabulated); nevertheless, the predictive power for market returns is noticeably stronger for SI than for PC1 (rows 4 and 8). Our results indicate that the value premium's market beta correlates closely with the conditional equity premium.

In Panel B of Table 2, we test the hypotheses about the variation in the conditional beta across time. We reject the null hypothesis that the beta is 0 at the 1% significance level. Moreover, we find strong evidence against the null hypothesis that the conditional beta is constant. We fail to reject the null hypothesis that the conditional beta is a linear function of the state variables INF, PE, and UE at the conventional significance level, and untabulated results show that the relationship between the conditional beta and the single index is essentially linear. This novel finding, which is in contrast with that reported by Wang (2003), who uses a fully nonparametric model, provides the first empirical justification for the linear specification of the conditional beta adopted in the extant studies.

Panel C of Table 2 investigates cyclical variation in the conditional alpha. We overwhelmingly reject the null hypothesis that the conditional alpha is 0. Interestingly, our evidence reveals a significant nonlinear dependence of the conditional alpha on the single index: We reject the null hypothesis that the conditional alpha is a linear function of the single index at the 10% significance level. Specifically, untabulated results indicate that the conditional alpha is more sensitive to the single index during business recessions (when the single index is low) than during business expansions (when the single index is high). As a result, Figure 3 shows that the conditional alpha falls sharply and becomes negative during severe business downturns such as the Great Recession but is significantly positive and essentially flat otherwise. The novel evidence from Figure 3 lends

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

empirical support to the rare-disaster risk model analyzed by Bai et al. (2015). These authors show, using simulated data, that the conditional alpha is positive and flat in normal times but becomes insignificant or negative when disaster risk materializes. Their model also implies that disaster risk leads to a spike in the conditional beta, as we document in Figure 1.

The value premium has a significantly positive alpha of 0.47% per month at the 1% significance level when we use the unconditional CAPM (untabulated). Panel D of Table 2 shows that the alpha decreases noticeably, to 0.38% per month, in the conditional CAPM. Untabulated results show that the 20% reduction in the alpha is also statistically significant at the 5% significance level.[9] These findings are consistent with the notion that the conditional CAPM helps explain the value premium because its risk exposure is larger during business recessions, when the conditional equity premium is high, than during business expansions, when the conditional equity premium is low. Nevertheless, we find that the alpha remains significantly positive at the 1% significance level even when we control for the time-varying conditional beta. Again, this finding is consistent with the rare-disaster model by Bai et al. (2015). Similar to the peso problem, we observe a positive alpha in finite samples because it is a compensation for expected but unrealized rare disasters. That is, as we document in Figure 3, the conditional alpha is significantly positive during normal times, when the economy is spared from catastrophic shocks. Moreover, consistent with the model implication of Bai et al. (2015) that value stocks are more vulnerable to rare disasters than are growth stocks because of their higher investment adjustment costs, untabulated results show that the conditional alpha is positive for value stocks but is negligible for growth stocks.

B. Realized Beta as a Conditioning Variable

In Section IV.A, we found that the conditional CAPM fails to explain fully the value premium. One possible explanation is that our specification has an underconditioning bias because we omit some important state variables. Boguth et al. (2011) suggest that the lagged realized beta ($BETA_R$) is a good instrumental variable for the conditional beta. Nevertheless, because it is not necessarily an efficient measure of the conditional beta, the macroeconomic and financial variables may provide additional information about the conditional beta beyond $BETA_R$. To address these issues, we include $BETA_R$ as an additional candidate conditioning variable in the variable-selection procedure. For the July 1963–Dec. 2012 period, we select the model with $BETA_R$, INF, and PE as the conditioning variables.

Table 4 reports the main estimation results of the single-index varying-coefficient model with $BETA_R$, INF, and PE as the conditioning variables. Panel A shows that the single index correlates positively with $BETA_R$. Because the

[9]Extant studies provide no formal test statistic for comparing the alphas from the single-index varying-coefficient conditional CAPM with the alpha from the unconditional CAPM. We address this issue using a bootstrapping method of classical sampling with replacement to obtain the empirical distribution of the difference between the two alphas. As a robustness check, we also estimate a linear conditional CAPM with UE, PE, and INF as the conditioning variables. Using the generalized method of moments (GMM) approach proposed by Boguth et al. (2011), we again find that the reduction in the alpha from the unconditional CAPM to the conditional CAPM is statistically significant at the 5% level.

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

TABLE 4
Controlling for Realized Beta

Table 4 reports the estimation results of the single-index varying-coefficient model with the value premium's realized beta, $BETA_R$, as a candidate conditioning variable, in addition to standard macroeconomic and financial variables. Panel A reports the single-index parameter estimates of the selected conditioning variables via an exhaustive variable-selection procedure. INF is inflation. PE is the price–earnings ratio. Panels B, C, and D report statistical tests on the conditional beta, the conditional alpha, and the long-run alpha (α_{LR}), respectively. Tests on the conditional beta and alpha are based on the Wald statistics in equation (8). Tests on the long-run alpha are based on equation (9). All covariance matrices and standard errors (SE) (reported in parentheses) are calculated using the wild bootstrap. The monthly sample spans the July 1963–Dec. 2012 period.

Parameter (Variable)		Estimate (SE)
Panel A. Single-Index Parameter Estimates		
γ_1(BETA$_R$)		0.3352 (0.1583)
γ_2(INF)		−0.8533 (0.2866)
γ_3(PE)		−0.3994 (0.1424)
Hypothesis	Wald Statistic	*p*-Value
Panel B. Tests on Conditional Beta		
$H_0: \beta = 0$	140.30	0.0000
$H_0: \beta =$ Constant	85.69	0.0000
$H_0: \beta =$ Linear	10.64	0.4165
Panel C. Tests on Conditional Alpha		
$H_0: \alpha =$ Constant	16.18	0.0235
$H_0: \alpha =$ Linear	9.58	0.1436
Hypothesis		Estimate (SE)
Panel D. Tests on Long-Run Alpha		
$H_0: \alpha_{LR} = 0$		0.0041 (0.0011)

conditional beta increases monotonically with the single index (untabulated), our results indicate that the lagged realized beta correlates positively with the conditional beta. The single index also correlates negatively with INF and PE, again supporting the notion that the conditional beta changes countercyclically across time. Panel B shows that we reject at the 1% significance level the null hypothesis that the conditional beta is 0 and the null hypothesis that the conditional beta is constant. However, we fail to reject the null hypothesis at the 10% significance level that the conditional beta is a linear function of the conditioning variables. Panel C shows that we reject the null hypothesis that the conditional alpha is constant at the 5% significance level, and we reject the null hypothesis that the conditional alpha is linear in the single index at the 15% significance level. Overall, Panel D shows that the long-run alpha remains significantly positive at the 1% level. Therefore, including the realized beta in the conditional CAPM does not change our main findings in any qualitative manner.

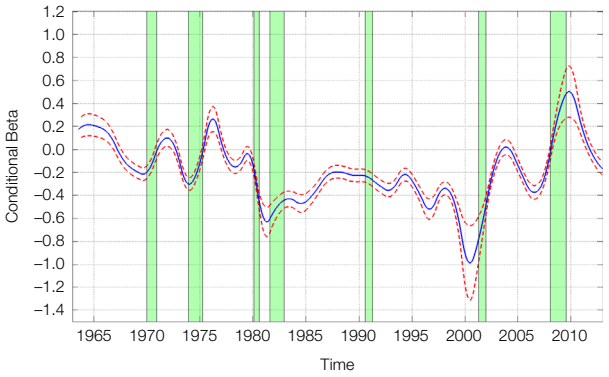

C. Ang and Kristensen's Time-Varying Beta

Ang and Kristensen (2012) use a nonparametric approach to model the value premium's conditional beta as a flexible function of the calendar time. In contrast to our findings, these authors document a rather weak relation between their beta estimates and business cycles. For comparison, in this section, we adopt their specification to estimate the time-varying beta and then use it as an additional candidate conditioning variable in our variable-selection procedure. Ang and Kristensen (2012) use daily return data and the local polynomial smoothing

FIGURE 4
Ang and Kristensen's Conditional Beta

Figure 4 plots monthly estimates of Ang and Kristensen's (2012) conditional beta of the value premium, $BETA_{AK}$ (solid line) along with its 95% confidence intervals (dashed lines). The sample spans the July 1963–Dec. 2012 period. Shaded areas indicate National Bureau of Economic Research (NBER) recession periods.

algorithm in their estimation and then construct the monthly beta using some bandwidth-controlling criterion. In this paper, we estimate the monthly beta using monthly return data, and we find qualitatively similar results using both the penalized spline smoothing algorithm and the local polynomial smoothing algorithm. For brevity, we report the results only for the former; the results for the latter are available from the authors.

Figure 4 plots the estimated value premium's time-varying beta based on Ang and Kristensen's (2012) model over the post-1963 sample period. Interestingly, it appears to increase during business recessions and to decrease during business expansions. To investigate formally whether the estimated time-varying beta changes countercyclically across time, we regress it on the 3 most important conditioning variables (i.e., PE, INF, and UE) that we identify via the exhaustive variable-selection procedure. Panel E of Table 5 shows that the estimated time-varying beta ($BETA_{AK}$) correlates negatively and significantly with PE and INF at the 1% level. It also correlates positively with UE, albeit the correlation is statistically insignificant at the 10% level. Therefore, we again find countercyclical variation in the alternative measure of the value premium's conditional beta. Our results differ from those of Ang and Kristensen (2012), possibly because of the bandwidths that these authors choose when constructing monthly conditional beta from nonparametric estimation based on the daily data. Moreover, we extend Ang and Kristensen's (2012) sample from Dec. 2006 to Dec. 2012 and thus include the 2008 subprime loan crisis, during which the value premium's conditional beta has a big spike (Figure 4).

Similar to the realized beta, Ang and Kristensen's (2012) time-varying beta may provide important information about the conditional beta. We address this issue in Table 5. Panel A shows that we select the time-varying beta estimated using Ang and Kristensen's (2012) specification, $BETA_{AK}$, along with DEF, TERM, and INF as the conditioning variables. Because the conditional beta increases

TABLE 5

Controlling for Ang and Kristensen's Conditional Beta

Table 5 reports the estimation results of the single-index varying-coefficient model with Ang and Kristensen's (2012) conditional beta of the value premium ($BETA_{AK}$) as a candidate conditioning variable, in addition to standard macroeconomic and financial variables. Panel A reports the single-index parameter estimates of the selected conditioning variables via an exhaustive variable-selection procedure. DEF is the default premium. TERM is the term premium. INF is inflation. Panels B, C, and D report statistical tests on the conditional beta, the conditional alpha, and the long-run alpha, respectively. Tests on the conditional beta and alpha are based on the Wald statistics in equation (8). Tests on the long-run alpha are based on equation (9). All covariance matrices and standard errors (SE) (reported in parentheses) are calculated using the wild bootstrap. Panel E reports the ordinary least squares (OLS) regression results of regressing the estimated time-varying beta based on Ang and Kristensen (2012) on the three most important conditioning variables (i.e., INF, PE, and UE). The monthly sample spans the July 1963–Dec. 2012 period.

Parameter (Variable)			Estimate (SE)
Panel A. Single-Index Parameter Estimates			
γ_1(BETA$_{AK}$)			0.1506 (0.0896)
γ_2(DEF)			0.8490 (0.3425)
γ_3(TERM)			−0.4281 (0.1682)
γ_4(INF)			−0.2707 (0.1445)
Hypothesis		Wald Statistic	*p*-Value
Panel B. Tests on Conditional Beta			
$H_0: \beta = 0$		167.28	0.0000
$H_0: \beta =$ Constant		93.60	0.0000
$H_0: \beta =$ Linear		0.47	0.9981
Panel C. Tests on Conditional Alpha			
$H_0: \alpha = 0$		29.82	0.0002
$H_0: \alpha =$ Constant		6.97	0.4325
$H_0: \alpha =$ Linear		0.35	0.9992
Hypothesis			Estimate (SE)
Panel D. Tests on Long-Run Alpha			
$H_0: \alpha_{LR} = 0$			0.0042 (0.0010)
Variables	Estimate (SE)	*t*-Value	*p*-Value
Panel E. OLS Regression of $BETA_{AK}$ onto INF, PE, and UE			
Intercept	0.17 (0.05)	3.57	0.0004
INF	−3.04 (0.52)	−5.88	0.0000
PE	−1.47 (0.15)	−9.50	0.0000
UE	0.05 (0.07)	0.65	0.5149

monotonically with the single index (untabulated), the results reported in Panel A suggest that $BETA_{AK}$ correlates positively with the conditional beta. Moreover, we find that the conditional beta correlates positively with DEF and correlates negatively with TERM and INF, revealing its countercyclical variation. In Panel B, we reject the null hypotheses that the conditional beta is 0 or constant but fail to reject the null hypothesis that the conditional beta is a linear function of the selected state variables. In Panel C, we reject the null hypothesis that the conditional alpha is 0 but do not reject the null hypothesis that the conditional alpha is constant. Overall, Panel D shows that the conditional CAPM fails to fully explain the value premium, despite countercyclical variation in the value premium's conditional beta. Therefore, controlling for Ang and Kristensen's (2012) conditional beta also does not change our main findings qualitatively.

D. Different Samples

Whereas many authors (e.g., Ang and Kristensen (2012)) focus on the post-1963 sample, as a robustness check, we estimate the conditional CAPM using a

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

longer sample, spanning the Jan. 1949–Dec. 2012 period, over which we have observations for all the variables. The results are qualitatively similar to those obtained from the post-1963 sample. We identify INF, PE, and UE as the most relevant state variables. The conditional beta is countercyclical because it correlates positively with INF and PE and correlates negatively with UE. We reject the null hypothesis that the conditional beta is 0 or constant but fail to reject the null hypothesis that the conditional beta is a linear function of the selected state variables. In addition, the conditional alpha drops steeply toward 0 during severe recessions but is significantly positive and essentially flat otherwise. Overall, the conditional CAPM has a long-run alpha of about 0.33% per month, a noticeable reduction from the 0.46% found for the unconditional CAPM. For brevity, we do not report these results here, but they are available from the authors.

As we mentioned at the beginning of the empirical findings, several studies show that the value premium poses a challenge to the unconditional CAPM for the post-1963 sample but not for the pre-1963 sample. To address this issue, we estimate the conditional CAPM using the full sample (Jan. 1927–Dec. 2012) and two subsamples (Jan. 1927–June 1963 and July 1963–Dec. 2012). Because the unemployment rate is available only from Jan. 1949, for direct comparison of all three samples, we exclude UE from our set of candidate state variables. We summarize our main results in Table 6. For the full sample, we find that both macroeconomic variables (INF and IP) and financial variables (DEF, PE, and TERM) are significant conditioning variables for the value premium's conditional beta. The results are qualitatively similar when we include $BETA_R$ as an additional conditioning variable. More importantly, similar to the results obtained from the post-1963 sample, Figure 2 shows that the value premium's conditional beta exhibits strong countercyclical variation in the full sample as well. Nevertheless, the conditional CAPM fails to explain the value premium over the full sample. The variable-selection results are similar for the pre-1963 sample. Both the macroeconomic variable (IP) and the financial variables (DEF, PE, and TERM) are significant conditioning variables for the value premium's conditional CAPM, although we confirm that the unconditional CAPM explains the value premium for the

TABLE 6

Variable-Selection Results and Long-Run Alpha Estimates in Different Samples

Table 6 summarizes the variable-selection results and long-run alpha estimates for different samples. The full sample spans the Jan. 1927–Dec. 2012 period. The pre-1963 sample spans the Jan. 1927–June 1963 period. The post-1963 sample spans the July 1963–Dec. 2012 period. α_{LR} is the long-run alpha defined in equation (9). $BETA_R$ is the value premium's realized beta. DEF is the default premium. INF is inflation. IP is industrial production. PE is the price–earnings ratio. TERM is the term premium. *** indicates significance at the 1% level.

Sample	Variable Pool	Best Variable Set	α_{LR}
Full sample	No $BETA_R$	DEF, INF, IP, PE, TERM	0.0031***
	Include $BETA_R$	DEF, INF, IP, PE, $BETA_R$	0.0025***
Pre-1963 sample	No $BETA_R$	DEF, IP, PE, TERM	0.0014
	Include $BETA_R$	DEF, IP, PE, TERM	0.0014
Post-1963 sample	No $BETA_R$	INF, PE, TERM	0.0043***
	Include $BETA_R$	INF, PE, $BETA_R$	0.0040***

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

Jan. 1927–June 1963 period. For the post-1963 sample, when we exclude UE as a conditioning variable, TERM becomes a significant conditioning variable along with INF and PE. To summarize, the result that the value premium's conditional beta changes countercyclically across time is robust to the full sample and to the pre-1963 sample.

V. Conclusion

We revisit whether the conditional CAPM helps explain the value premium using a general framework that has two novel features. First, it allows for a nonlinear dependence of the conditional alpha, beta, and volatility on the state variables and nests the linear specification as a special case. Second, we adopt an exhaustive variable-selection method to choose the most relevant conditioning variables from a large set of candidate state variables. Furthermore, we consider key aggregate economic activity gauges as candidate conditioning variables, in addition to the stock market return and variance predictors and realized beta measures that are commonly used in previous studies.

We find strong countercyclical variation in the value premium's market beta. We also uncover a novel nonlinear dependence of the conditional alpha on business conditions: It decreases sharply and even becomes negative during severe economic downturns and is significantly positive and essentially flat otherwise. The conditional CAPM performs better than the unconditional CAPM; however, it does not fully explain the value premium either. Moreover, the value premium puzzle comes mainly from value stocks: The unconditional alpha is significantly positive for value stocks but is negligible for growth stocks. These findings are broadly consistent with the investment-based model proposed by Bai et al. (2015), in which rare disasters generate a nonlinear dependence of the alpha on business cycles and are responsible for the failure of CAPM in finite samples.

In this paper, we focus on the value premium to illustrate the empirical applications of our novel statistical specification for three reasons. First, it is arguably the most prominent asset pricing anomaly. Second, previous empirical studies have intensively investigated whether it is explained by the conditional CAPM. Last, various theoretical explanations have been proposed for it, and they provide important guidance for our empirical analysis. In future studies, it will be interesting to apply the single-index model systematically to other important CAPM-related anomalies to shed light on their theoretical explanations.

Appendix A. Reparameterization and Fixed-Point Algorithm

In Appendix A, we provide the technical details for the reparameterization of the single-index parameters and the estimation using the fixed-point algorithm.

In statistical literature on single-index and related models, to ensure the identifiability of single-index parameters, we commonly impose the constraints of unit norm and positive first component, that is, $\|\boldsymbol{\gamma}\| = 1$ and $\gamma_1 > 0$ (see, e.g., Carroll et al. (1997), Yu and Ruppert (2002)). Let $\gamma_1 = \sqrt{1-(\gamma_2^2+\cdots+\gamma_d^2)}$, where $\sum_{j=2}^{d}\gamma_j^2 < 1$; thus, the

https://doi.org/10.1017/S0022109017000382 Published online by Cambridge University Press

unconstrained single-index parameters are $\boldsymbol{\varphi}=(\gamma_2,\gamma_3,\ldots,\gamma_d)^{\mathsf{T}}$.[10] Denote $\boldsymbol{\theta}=(\boldsymbol{\gamma}^{\mathsf{T}},\boldsymbol{\delta}_a^{\mathsf{T}},\boldsymbol{\delta}_b^{\mathsf{T}},\boldsymbol{\delta}_2^{\mathsf{T}})^{\mathsf{T}}$ and $\tilde{\boldsymbol{\theta}}=(\boldsymbol{\varphi}^{\mathsf{T}},\boldsymbol{\delta}_a^{\mathsf{T}},\boldsymbol{\delta}_b^{\mathsf{T}},\boldsymbol{\delta}_2^{\mathsf{T}})^{\mathsf{T}}$ as the parameter vector before and after parameterization. The Jacobian matrix of this transformation is

$$\text{(A-1)}\qquad \mathbf{J}(\tilde{\boldsymbol{\theta}}) \;=\; \begin{bmatrix} -(1-\|\boldsymbol{\varphi}\|^2)^{-1/2}\boldsymbol{\varphi}^T & \mathbf{0} \\ \mathbf{I}_{d-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{\dim(\boldsymbol{\delta}_a)+\dim(\boldsymbol{\delta}_b)+\dim(\boldsymbol{\delta}_2)} \end{bmatrix}.$$

All inference results in Section II.E are for the reparameterized $\tilde{\boldsymbol{\theta}}$. We can formulate test statistics concerning the original parameters $\boldsymbol{\theta}$ by the inverse transformation using the Jacobian matrix. For example, the Fisher information in Theorem 1 becomes $\mathbf{J}(\tilde{\boldsymbol{\theta}})\mathbf{I}^{-1}(\tilde{\boldsymbol{\theta}})\mathbf{J}(\tilde{\boldsymbol{\theta}})^{\mathsf{T}}$, and the sandwich estimator of the covariance matrix becomes $\mathbf{J}(\tilde{\boldsymbol{\theta}})\boldsymbol{\Omega}_n(\tilde{\boldsymbol{\theta}}(\boldsymbol{\lambda}))\mathbf{J}(\tilde{\boldsymbol{\theta}})^{\mathsf{T}}$.

We adapt the fixed-point algorithm (Cui et al. (2011)) to penalized spline estimation in our single-index varying-coefficient models and find computationally promising results. Specifically, given $\boldsymbol{\delta}_1$, to obtain the single-index parameter estimates $\boldsymbol{\gamma}$ in equation (3), we let the first derivatives of the squared loss with respect to γ_s be zeros. Note that the roughness penalty terms vanish as the penalty is only on the spline coefficients. Define

$$\text{(A-2)}\quad M_s \;=\; \sum_{t=1}^{n}(R_{t+1}-\mathbf{B}_{a,t}\boldsymbol{\delta}_a-\mathbf{B}_{b,t}\boldsymbol{\delta}_b R_{m,t+1})(\mathbf{B}'_{a,t}\boldsymbol{\delta}_a+\mathbf{B}'_{b,t}\boldsymbol{\delta}_b R_{m,t+1})z_{s,t},\quad s=1,\ldots,d,$$

where $\mathbf{B}'_{\xi,t}(\xi=a,b)$ is the first derivative of the spline basis evaluated at $\mathbf{z}_t$, and define $\mathbf{M}=(M_1,\ldots,M_d)$. Setting $\mathbf{M}=0$ and by the chain rule, we obtain the $d-1$ equations

$$\begin{cases} \gamma_2 M_1 &= \gamma_1 M_2, \\ &\vdots \\ \gamma_d M_1 &= \gamma_1 M_d, \end{cases}$$

which have the solution

$$\begin{cases} \gamma_1 &= \dfrac{||M_1||}{||\mathbf{M}||}, \\ \gamma_s^2 &= \dfrac{||M_s||^2}{||\mathbf{M}||^2}, \quad 2\le s\le d, \\ \operatorname{sign}(\gamma_s M_1) &= \operatorname{sign}(M_s), \quad 2\le s\le d. \end{cases}$$

This system equals $\boldsymbol{\gamma}M_1/||\mathbf{M}||=|M_1|/||\mathbf{M}||\times\mathbf{M}/||\mathbf{M}||$, which automatically handles the constraints $||\boldsymbol{\gamma}||=1$ and $\gamma_1>0$. For fast convergence and robustness of the fixed-point algorithm, we add some constant C to $||\mathbf{M}||$ to avoid dividing by a small value. To achieve this, we add $C\boldsymbol{\gamma}$ to both sides, and after transformation we obtain

$$\text{(A-3)}\qquad \boldsymbol{\gamma} \;=\; \frac{C}{M_1/(||\mathbf{M}||+C)}\boldsymbol{\gamma}+\frac{M_1/(||\mathbf{M}||^2)}{M_1/(||\mathbf{M}||+C)}\mathbf{M}.$$

[10] An alternative way of reparameterization is letting $\gamma_1=1$ and the new parameter

$$\boldsymbol{\varphi} \;=\; \frac{(1,\gamma_2,\gamma_3,\ldots,\gamma_d)}{\sqrt{1+\sum_{j=2}^{d}\gamma_j^2}}.$$

However, this reparameterization may not be suitable for the fixed-point algorithm proposed here.

https://doi.org/10.1017/S0021109017000382 Published online by Cambridge University Press

We choose the constant C properly to avoid dividing by 0 and refer further discussions to Cui et al. (2011).

We describe the 2-phase iterative algorithm for iteratively estimating the mean and volatility functions as follows:

Step 0. Initialization

Initialize the single-index parameter $\boldsymbol{\gamma}$. For example, we can use the usual OLS estimates for linear regression $R_{t+1} = (\mathbf{z}_t + \mathbf{z}_t R_{m,t+1})\boldsymbol{\gamma} + \epsilon_{t+1}$. Alternatively, we can use random initial points from the unit sphere. Normalize $\boldsymbol{\gamma}$ such that $\boldsymbol{\gamma} = \text{sign}(\gamma_1)\boldsymbol{\gamma}/||\boldsymbol{\gamma}||$.

Step 1. Mean Estimation

1a) Spline Coefficients Calculation. Given $\widehat{\boldsymbol{\gamma}}$, compute spline coefficients of $\alpha(\cdot)$ and $\beta(\cdot)$, or $\widehat{\boldsymbol{\delta}}_1$ and the estimated value premium $\widehat{R}_{t+1}$. We calculate spline coefficients using $\widehat{\boldsymbol{\delta}}_1 = (\mathbf{X}^{\mathrm{T}}\mathbf{X} + n\boldsymbol{\lambda}_1\mathbf{D}_1)^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{R}$ and estimate value premium using $\widehat{\mathbf{R}} = \mathbf{X}\widehat{\boldsymbol{\delta}}_1$, where $\mathbf{X}$ is the design matrix.

1b) Fixed-Point Algorithm. Given $\widehat{\boldsymbol{\delta}}_1$ and $\widehat{\mathbf{R}}$, calculate the first derivatives for equation (A-2). Use the fixed-point algorithm to update single-index parameters $\boldsymbol{\gamma}$ using equation (A-3), and normalize $\boldsymbol{\gamma}$ such that $\boldsymbol{\gamma} = \text{sign}(\gamma_1)\boldsymbol{\gamma}/||\boldsymbol{\gamma}||$.

Repeat 1a) and 1b) until $\max_{1\le s\le d} |\boldsymbol{\gamma}_{s,\text{new}} - \boldsymbol{\gamma}_{s,\text{old}}| \le \text{tol}$, where tol is the prescribed tolerance level.

Step 2. Volatility Estimation and Reweighting

Given $\widehat{\boldsymbol{\gamma}}$ and $\widehat{\boldsymbol{\delta}}_1$, estimate $\boldsymbol{\delta}_2$ by minimizing the penalized negative log-likelihood function in expression (4). Use the updated squared volatility estimates $\widehat{\sigma}^2(\mathbf{z}_t\widehat{\boldsymbol{\gamma}})$ to reestimate the mean spline coefficients by the (penalized) weighted least square estimator $\widehat{\boldsymbol{\delta}}_1 = (\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{X} + n\boldsymbol{\lambda}_1\mathbf{D})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{R}$, where $\mathbf{W} = \text{diag}\{1/\widehat{\sigma}^2(\mathbf{z}_t\widehat{\boldsymbol{\gamma}})\}$ is the diagonal weight matrix.

In our implementation, we find that two or three iterations of Step 1 and Step 2 are sufficient, as noted by Carroll, Wu, and Ruppert (1988).

Appendix B. Wild Bootstrap Procedure

In Appendix B, we describe in detail the wild bootstrap procedure for obtaining the covariance matrix.

(1) Fit the single-index varying-coefficient model to obtain $\widehat{R}_{t+1} = \mathbf{B}_a(\mathbf{z}_t\widehat{\boldsymbol{\gamma}})\widehat{\boldsymbol{\delta}}_a + \mathbf{B}_b(\mathbf{z}_t\widehat{\boldsymbol{\gamma}})\widehat{\boldsymbol{\delta}}_b R_{m,t+1}$ and the residual $\widehat{\epsilon}_{t+1} = R_{t+1} - \widehat{R}_{t+1}$ $(t = 1,\ldots,n)$.

(2) Center the residual $\epsilon^*_{t+1} = \widehat{\epsilon}_{t+1} - \bar{\widehat{\epsilon}}_{t+1}$ $(t = 1,\ldots,n)$, where $\bar{\widehat{\epsilon}}_{t+1}$ is the mean of residuals.

(3) Create the bootstrap sample using $\widehat{R}_{t+1} + v_{t+1}\epsilon^*_{t+1}$ $(t = 1,\ldots,n)$, where v_{t+1} is a random variable of standard normal distribution.[11]

Repeat the final step to create N resamples. The sample covariance matrix and standard errors of the long-run alpha can be calculated based on the N estimates.

[11] We have also implemented the wild bootstrap weighting scheme of Mammen (1993), where the random weight takes the form

$$v_{t+1} = \begin{cases} -(\sqrt{5}-1)/2 & \text{with probability } (\sqrt{5}+1)/(2\sqrt{5}), \\ (\sqrt{5}+1)/2 & \text{with probability } (\sqrt{5}-1)/(2\sqrt{5}). \end{cases}$$

The testing results agree with those found when using standard normal weight, as in Wu (1986).
